Localization of the site of the unknown primary tumor is critical for surgical treatment of patients presenting with neuroendocrine tumor (NET) with metastases. **Methods:** Forty patients with metastatic NET and unknown primary site underwent ^{68}Ga -DOTATOC PET/CT in a single-site prospective study. The ^{68}Ga -DOTATOC PET/CT was considered true-positive if the positive primary site was confirmed by histology or follow-up imaging. The scan was considered false-positive if no primary lesion was found corresponding to the ^{68}Ga -DOTATOC-positive site. All negative scans for primary tumor were considered false-negative. A scan was classified unconfirmed if ^{68}Ga -DOTATOC PET/CT suggested a primary, however, no histology was obtained and imaging follow-up was not confirmatory. **Results:** The true-positive, false-positive, false-negative, and unconfirmed rates for unknown primary tumor were 38%, 7%, 50%, and 5%, respectively. **Conclusion:** ^{68}Ga -DOTATOC PET/CT is an effective modality in the localization of unknown primary in patients with metastatic NET.

Key Words: neuroendocrine; PET/CT; ^{68}Ga -DOTATOC; neuroendocrine tumor; unknown primary

J Nucl Med 2017; 58:1054–1057

DOI: 10.2967/jnumed.116.180984

Between 9% and 19% of patients with neuroendocrine tumors (NETs) present with metastatic disease with an unknown primary tumor site (1). Localization of the primary tumor is highly relevant in the management of this patient population because complete resection of the primary tumor and metastases is the treatment goal for patients with well-differentiated NET metastases (2). Even if the metastases are not completely resectable, debulking surgery can improve symptom control in patients with endocrine symptoms and may improve survival (2–4).

The standard imaging for staging of NETs includes CT and MRI as well as somatostatin receptor scintigraphy. CT and MRI are

limited for evaluation of primary small bowel NETs; somatostatin receptor imaging with ^{111}In -octreotide (Octreoscan; Mallinckrodt Pharmaceuticals) also shows limited detectability, with only 37% of small bowel primary NETs detected preoperatively with ^{111}In -octreotide (5). More recently, somatostatin receptor imaging with positron emitters has been developed using ^{68}Ga (a generator product with a half-life of 68 min) and DOTA as chelator. The most widely studied ^{68}Ga -DOTA-octreotide analogs for PET imaging are ^{68}Ga -DOTATATE, ^{68}Ga -DOTATOC, and ^{68}Ga -DOTANOC. All of these radiopharmaceuticals have higher affinity than ^{111}In -octreotide for the somatostatin receptor subtype 2, the primary target in NETs, and are more sensitive than ^{111}In -octreotide in the detection of NET lesions (6–8).

The objective of this study was to evaluate the accuracy of ^{68}Ga -DOTATOC PET/CT imaging in the localization of the site of the unknown primary tumor in patients with metastatic NET.

MATERIALS AND METHODS

Patients

A single-center prospective study was performed to evaluate the safety and efficacy of ^{68}Ga -DOTATOC PET/CT in patients with a previous diagnosis of or suspected NET. A database of enrolled subjects was created and classified according to the scan indications, which included initial staging and restaging of NETs, diagnosis of NET in patients with suspected disease, and localization of unknown primary in patients with metastatic NET. Patients with histologically proven NET metastases and an unknown primary were included in this analysis. This study was performed under a physician-sponsored Investigational New Drug application from the U.S. Food and Drug Administration for ^{68}Ga -DOTATOC (IND# 114,398). The study protocol was approved by the University of Iowa Institutional Review Board, and all subjects signed a written informed consent form. The clinical trial was listed in clinicaltrials.gov (NCT01619865).

^{68}Ga -DOTATOC PET/CT Imaging

^{68}Ga -DOTATOC was synthesized using an automated $^{68}\text{Ge}/^{68}\text{Ga}$ generator (IGG100; Eckert & Ziegler) coupled with a ModularLab PharmTracer synthesis module (Eckert & Ziegler) as previously described (9–12). Briefly, ^{68}Ga was eluted from the generator with 0.1 M hydrochloric acid (6 mL) and passed through an in-line cation exchange resin (STRATA-XC; Phenomenex). Purified ^{68}Ga was then eluted with 98% acetone/0.02 M HCl (0.8 mL) to a glass reaction vessel containing DOTATOC (39 nmol, 55 μg) in sodium acetate buffer, pH 4 (2 mL). Radiolabeling was performed at 95°C for 6 min, and acetone was removed by vent to waste during the radiolabeling step. After being

radiolabeled, ^{68}Ga -DOTATOC was transferred to an in-line SPE tC-18 cartridge (Waters); free ^{68}Ga was removed by saline rinse. Pure ^{68}Ga -DOTATOC was first eluted with 47.5% ethanol:water (1.2 mL) to the product vial via a 0.22- μm sterilizing filter followed by isotonic saline for injection (7 mL). Quality control parameters of radiochemical and radionuclidic purity, half-life, pH, endotoxin content, and sterility were measured by standard techniques.

Whole-body images from the top of the head to proximal thighs were obtained on a Siemens Biograph PET/CT scanner after a 60-min uptake period after the intravenous administration of 148–185 MBq of ^{68}Ga -DOTATOC. A low-dose, noncontrast whole-body CT scan (30–60 mAs, 120 kV, 5-mm slice thickness, and pitch of 0.8) was acquired for attenuation correction. PET/CT images were iteratively reconstructed using 4 iterations and 8 subsets with a 7-mm gaussian postprocessing filter.

Data Analysis

PET/CT images were read qualitatively by an experienced nuclear medicine specialist, with focal uptake of ^{68}Ga -DOTATOC above normal background considered positive for NET. The clinical indication of the scan and previous conventional imaging studies were available to the reading physicians. The scan was considered true-positive if the primary lesion suggested by ^{68}Ga -DOTATOC PET/CT was confirmed by histology or follow-up imaging. A scan was considered false-positive if no primary lesion was found corresponding to a ^{68}Ga -DOTATOC-positive site on surgery, endoscopy, or imaging follow-up. All ^{68}Ga -DOTATOC PET/CT scans negative for primary tumor were considered false-negative. None of the scans was considered true-negative for primary tumor because all patients had histologically proven NET metastases (present or previously resected). A scan was classified as unconfirmed if a potential primary tumor site was identified on ^{68}Ga -DOTATOC PET/CT, but no histology was obtained and imaging and clinical follow-up did not confirm the lesion. The effectiveness of ^{68}Ga -DOTATOC PET/CT scans was measured with regard to identification of primary tumors.

RESULTS

Patients

Forty patients, 23 men and 17 women with an age range of 20–75 y (55 ± 12 y), with metastatic NET and unknown primary site, were imaged with ^{68}Ga -DOTATOC PET/CT. Before ^{68}Ga -DOTATOC PET/CT scanning, all patients underwent a CT or MRI of the abdomen–pelvis (conventional imaging) that failed to localize a primary tumor. Conventional imaging was obtained within a median of 3 mo before ^{68}Ga -DOTATOC PET/CT (range, 1–27 mo; in 37 patients within 1 y). Seventeen patients also underwent an ^{111}In -octreotide scan within 1 y of ^{68}Ga -DOTATOC PET/CT scanning (median, 4 mo). The metastatic sites identified before ^{68}Ga -DOTATOC PET/CT were the liver ($n = 29$); lymph nodes ($n = 8$); bones ($n = 6$); lungs and pleura ($n = 5$); peritoneum ($n = 2$); and skin, brain, or kidney lesions ($n = 1$ patient each). In 18 patients, the liver was the only known site of metastasis. The distribution of tumor grade for metastatic sites, available in 38 patients, was low-grade in 13 patients, intermediate-grade in 17 patients, and high-grade in 8 patients. The initial diagnosis of metastatic NET was made between 1 and 178 mo (median, 6.5 mo) before ^{68}Ga -DOTATOC PET/CT scanning; 20 scans were obtained within 6 mo of diagnosis, 6 scans within 6–12 mo, 10 scans within 1–5 y, and 4 scans more than 5 y after initial diagnosis of NET.

Localization of Unknown Primary

^{68}Ga -DOTATOC PET/CT was true-positive for primary tumor in 15 patients (38%; confidence interval, 23%–53%), unconfirmed positive in 2 patients (5%), false-positive in 3 patients (7%), and

false-negative in 20 patients (50%). The true-positive sites for primary NET on ^{68}Ga -DOTATOC were the pancreas in 6 patients, ileum in 8 patients, and retrorectal in 1 patient. The true-positive tumor sites were confirmed with histology in 11 of 15 patients and follow-up imaging in 4 of 15 patients. There was no significant difference in detection rate of the primary tumor between patients imaged within 1 y of diagnosis versus after 1 y (44% vs. 27%). The true-positive rate for primary tumor detection was 5 of 13 for patients with low-grade metastases, 7 of 17 for intermediate-grade metastases, and 2 of 8 for high-grade metastases, with no statistically significant difference between the groups. Among 11 primary tumors with histopathologic confirmation, 8 were low-grade and 3 were intermediate-grade. There were 3 false-positive scans, one in the ileum in an area of lymphoid hyperplasia found on surgical histopathology, one in the stomach with negative follow-up endoscopy, and another in the pancreatic head with negative conventional imaging and endoscopic ultrasound on follow-up. In 17 patients who underwent both ^{111}In -octreoscan and ^{68}Ga -DOTATOC within 1 y, there were 1 true-positive on ^{111}In -octreoscan (also positive on ^{68}Ga -DOTATOC) and 7 true-positive ^{68}Ga -DOTATOC ($P = 0.03$). The performance characteristics of ^{68}Ga -DOTATOC PET/CT in detection of unknown primary NETs are summarized in Table 1. Figures 1 and 2 show 2 true-positive scans of ileal and pancreatic primary NETs, and Figure 3 shows a false-positive scan in ileal lymphoid hyperplasia.

DISCUSSION

NETs of unknown primary are the third most common site of origin for NETs after rectal and pulmonary carcinoids, surpassing pancreatic and ileal primary sites (13). Identification of primary tumor is critical if curative intent therapy is planned with complete surgical resection of metastases and the primary tumor. Even in patients with unresectable liver metastases, a systematic review of the literature has found a potential benefit of resection of primary NET (3). In a multiinstitutional retrospective analysis of patients with metastatic liver disease from midgut NET, resection of the primary tumor was an independent predictor of survival, with a median survival of 9.92 y after resection of the primary versus 4.68 y for patients with no resection of the primary tumor (14). Improved survival was also reported in patients after resection of primary pancreatic tumor in metastatic NET in 882 patients, with a median survival of 5.42 y for patients who had resection versus 0.83 y for patients who did not have surgery for primary tumor (4). It should be noted, however, that these studies reporting improved survival after resection were limited in their retrospective nature and did not prospectively randomize patients to systemic therapy versus surgery.

In our study, ^{68}Ga -DOTATOC PET/CT identified the primary tumor in 38% of patients with metastases after conventional imaging

TABLE 1

Characteristic	Percentage
True-positive	38
Unconfirmed	5
False-positive	7
False-negative	50

FIGURE 1. ^{68}Ga -DOTATOC PET/CT images of patient with liver metastases on CT. In addition to multiple liver lesions, ^{68}Ga -DOTATOC PET/CT shows focus of increased uptake in right lower quadrant (arrows), consistent with ileal NET. Subcentimeter paracaval node is also visible (dashed arrow). Patient underwent resection of primary ileal NET and radiofrequency ablation of liver metastases.

failed to detect the primary lesion. ^{68}Ga -DOTATOC PET/CT was equally effective in localization of unknown primary tumor in low-grade and intermediate-grade metastases. The ^{68}Ga -DOTATOC PET/CT, however, led to unnecessary invasive procedures in 3 patients (8%). In 2 patients, variants of presumed normal uptake of ^{68}Ga -DOTATOC were considered sufficiently suspicious in the pancreatic head (uncinate process) and gastric fundus to recommend endoscopic procedures, both of which failed to identify a primary tumor. In a

FIGURE 2. ^{111}In -octreotide coronal and transaxial SPECT/CT images (top) and ^{68}Ga -DOTATOC coronal and transaxial PET/CT images (bottom) of patient with liver metastases presenting with Cushing syndrome and unknown primary. Multiple liver lesions were seen on both scans although many more on ^{68}Ga -DOTATOC PET/CT. Pancreatic body lesion is clearly identified on ^{68}Ga -DOTATOC PET/CT images (arrows) but not visualized on the ^{111}In -octreotide SPECT/CT scan obtained 2 mo before ^{68}Ga -DOTATOC PET/CT scan. Patient underwent distal pancreatectomy, adrenalectomy, and radiofrequency ablation of liver metastases.

third patient (Fig. 3), lymphoid hyperplasia in the ileum caused a false-positive scan that led to unnecessary small bowel resection. This likely reflected the high somatostatin receptor density in inflammatory bowel disease reported previously by somatostatin receptor autoradiography (15) and on ^{111}In -octreotide scintigraphy (16).

There are few reports of case series in the literature on patients with unknown primary tumors imaged with ^{68}Ga -DOTA-octreotide analogs (DOTATOC, DOTANOC, or DOTATATE). The largest study was reported by Prasad et al. with ^{68}Ga -DOTANOC in 59 patients with metastatic NETs (17). In this latter study, the reported detectability of primary tumor with ^{68}Ga -DOTANOC was higher at 59%, although 49% of the positive scans for primary tumor were unconfirmed and surgical histopathology was available in 17% of patients. There may be also differences in detectability of tumor between ^{68}Ga -DOTANOC and ^{68}Ga -DOTATOC PET/CT, although the receptor affinity of both agents is similar for somatostatin receptor subtype 2, the predominant somatostatin receptor on NETs, whereas ^{68}Ga -DOTANOC has significantly higher affinity for somatostatin receptor subtype 3 and somatostatin receptor subtype 5 (18). In another study by Schreiter et al., patients with metastatic NET and unknown primary underwent either ^{68}Ga -DOTATOC PET/CT ($n = 33$) or ^{111}In -octreotide SPECT/CT ($n = 50$) (19). The detection rate of 46% for the unknown primary site with ^{68}Ga -DOTATOC was similar to our findings and significantly better than 8% obtained with ^{111}In -octreotide. With ^{68}Ga -DOTATATE PET/CT, Alonso et al. reported a detection rate of 59% of primary tumor in 29 patients with metastatic NETs, with a change in management in 24% of patients (20). Findings of our study along with these studies clearly demonstrate the value of PET/CT with ^{68}Ga -DOTA-octreotide analogs in patients with unknown primary NETs and suggest that for this indication ^{68}Ga -labeled DOTATOC, DOTANOC, and DOTATATE may be equivalent. At the time of writing of this article, only ^{68}Ga -DOTATATE is approved by the U.S. Food and Drug Administration for clinical use and ^{68}Ga -DOTANOC and ^{68}Ga -DOTATOC are investigational.

FIGURE 3. False-positive ^{68}Ga -DOTATOC PET/CT in patient with ileal lymphoid hyperplasia. Liver metastases seen on whole-body coronal and transaxial PET/CT images (arrow, right top). Mild focal uptake noted in right lower quadrant (arrow) suspicious for ileal NET. Surgical histopathology of ileal resection showed lymphoid hyperplasia.

Our study had some limitations. Not all primary tumor sites suggested by ^{68}Ga -DOTATOC PET/CT could be verified by histology because some patients were not considered surgical candidates after workup. Although we were able to confirm or exclude primary tumor in 18 of 20 patients with positive ^{68}Ga -DOTATOC PET/CT by histology or imaging, 2 patients remained unconfirmed. The workup before ^{68}Ga -DOTATOC PET/CT scanning was not homogeneous because conventional imaging studies were done at different institutions with potentially different protocols and read by different readers.

CONCLUSION

^{68}Ga -DOTATOC PET/CT is an effective modality in localization of unknown primary tumor site in patients with metastatic NETs.
