PET imaging with the prostate-specific membrane antigen (PSMA)–targeted radioligand ^{68}Ga-PSMA-11 is regarded as a significant step forward in the diagnosis of prostate cancer (PCa). More recently, a PSMA ligand was developed that can be labeled with ^{68}Ga, ^{111}In, ^{177}Lu, and ^{90}Y. This ligand, named PSMA-617, therefore enables both diagnosis and therapy of PCa. The aims of this evaluation were to clinically investigate the distribution of ^{68}Ga-PSMA-617 in normal tissues and in PCa lesions as well as to evaluate the radiation exposure by the radioligand in PET imaging. **Methods:** Nineteen patients, most of them with recurrent PCa, were referred for ^{68}Ga-PSMA-617 PET/CT. The quantitative assessment of tracer uptake of several organs and of 53 representative tumor lesions was performed in 15 patients at 1 and 3 h after injection. In 4 additional patients, the same procedure was conducted at 5 min, 1 h, 2 h, 3 h, 4 h, and 5 h after injection. On the basis of the data for these 4 patients (mean injected dose, 231 MBq), the radiation exposure of a ^{68}Ga-PSMA-617 PET/CT was identified. **Results:** Intense tracer uptake was observed in the kidneys and salivary glands. In 14 of 19 patients (73.7%), at least 1 lesion suspected of being a tumor was detected at 3 h after injection. Of 53 representative tumor lesions selected at 3 h after injection, 47 lesions were visible at 1 h after injection. The mean tumor-to-background ratio for maximum standardized uptake value was 20.4 ± 17.3 (range, 2.3–84.0) at 1 h after injection and 38.2 ± 38.6 (range, 3.6–154.3) at 3 h after injection. The average radiation exposure (effective dose) was approximately 0.021 mSv/MBq. **Conclusion:** Within healthy organs, the kidneys and salivary glands showed the highest ^{68}Ga-PSMA-617 uptake. The radiation exposure was relatively low. ^{68}Ga-PSMA-617 shows PCa lesions with high contrast. Images obtained between 2 and 3 h after injection seem to be the best option with regard to radiotracer uptake and tumor contrast. Later images can help to clarify unclear lesions.

Key Words: prostate cancer; PET/CT; positron emission tomography; PSMA; prostate-specific membrane antigen; dosimetry

Prostate cancer (PCa) is the most common malignant tumor in men worldwide (*1,2*). After initial therapy, mainly by surgery or radiation, biochemical recurrence is frequent. At this constellation, searching for tumor relapses and metastases is challenging for conventional imaging modalities such as CT and MR imaging because of the often unsatisfying sensitivity and specificity. As a consequence, there has been the need to develop improved techniques to image PCa. In this context, many groups have focused on the prostate-specific membrane antigen (PSMA) as a promising biologic target for scintigraphic imaging and endoradiotherapy of PCa (*3,4*). PSMA is a transmembrane protein that is significantly overexpressed in most adenocarcinomas of the prostate gland, compared with other PSMA-expressing tissues. In addition, as already shown in the late 1990s, the neovasculature of many solid tumors also expresses PSMA (*5–7*).

During the last 2 decades, many efforts have been undertaken to develop PSMA ligands (*8–16*). One of these ligands, the small-molecule Glu-NH-CO-NH-Lys-(Ahx)-[^{68}Ga(HBED-CC)], also known as PSMA-11, PSMA^{HBED}, Glu-CO-Lys(Ahx)-HBED-CC, DKFZ-PSMA-11, PSMA-HBED-CC, PSMA-HBED, PSMA, or Prostamedix, developed at the German Cancer Research Center Heidelberg (DKFZ), has become the most clinically used radiotracer. This compound shows a strong binding affinity to PSMA and a highly efficient internalization into PCa cells (*17,18*).

The hitherto existing results of PET/CT imaging with ^{68}Ga-PSMA-11 demonstrate that this method could be a significant step forward in the diagnosis of recurrent PCa (*19–23*).

Meanwhile, modifications of PSMA-11 have resulted in the development of a novel small-molecule PSMA ligand, PSMA-617. In preclinical studies, this ligand showed a significantly improved binding affinity to PSMA and a highly efficient internalization into PCa cells (*24*). PSMA-617 can be labeled with ^{68}Ga, ^{177}Lu, ^{111}In, and ^{90}Y and, therefore, be used for PET imaging as well as for radioligand-based therapy. Preclinical assays of PSMA-617 showed inhibition constant (K_i) values of 2.3 ± 2.9 nM, demonstrating a significant improvement, compared with PSMA-11 (12.0 ± 2.8 nM). To our knowledge, PSMA-617 presents one of the highest binding affinities to the PSMA receptor that have been published thus far. In preclinical studies, tumor-to-background ratios of up to 1,058 were

observed at 24 h after injection. In addition, the internalization of the PSMA-617 into the PCa cells is highly effective (internalized fraction: 17.67% ± 4.34% injected activity/10^6 LNCaP cells [PSMA-11, 9.47% ± 2.56% injected activity/10^6 LNCaP cells]) (18,24).

Since 2013, ^{177}Lu-PSMA-617 has been increasingly used for radioligand therapy of metastatic PCa patients in several centers (to our knowledge, at least in Bad Homburg, Bonn, Cologne, Freiburg, Heidelberg, Istanbul, Melbourne, LMU Munich, and Münster) (25). However, the performance of this novel theranostic substance in the diagnosis of PCa in humans has not yet been evaluated and published. The aim of this evaluation was to clinically investigate the distribution of ^{68}Ga-PSMA-617 in normal tissues and in PCa lesions as well as to evaluate the radiation exposure by the radioligand in PET imaging.

MATERIALS AND METHODS

For this evaluation, we performed a retrospective analysis of 19 patients (Table 1) who underwent ^{68}Ga-PSMA-617 PET/CT to detect tumor lesions in the case of biochemical relapse of PCa, to exclude metastases before initial treatment of PCa, or to evaluate possible treatment with ^{177}Lu-PSMA-617 in progressive disease after multiple pretreatments. The mean age of the patients was 64 ± 8.2 y (range, 47–75 y; median, 66 y); patients had a median Gleason score of 7.0 (range, 5–9). The mean prostate-specific antigen (PSA) level was 5.0 ± 6.4 ng/mL (range, 0.1–24.3 ng/mL; median, 2.9 ng/mL).

All patients signed a written informed consent form for the purpose of anonymized evaluation and publication of their data. All reported investigations were conducted in accordance with the Helsinki Declaration and with our national regulations (German Medicinal Products Act, AMG §13 2b). This evaluation was approved by the ethics committee of the University of Heidelberg.

Follow-up was conducted until this article was submitted.

Radiotracer

The precursor compound PSMA-617 was produced at the German Cancer Research Center as recently published (24). However, the compound is commercially available from ABX advanced biochemical compounds. The radiopharmaceutical production of ^{68}Ga-PSMA-617 was adjusted to good manufacturing practice compliance as previously described for ^{68}Ga-PSMA-11 (17).

Imaging

Images were obtained with ^{68}Ga-PSMA-617, which was applied via intravenous bolus injection (mean, 203 ± 60 MBq; range, 68–295 MBq; median, 213 MBq). Variation of injected radiotracer activity was caused by the short half-life of ^{68}Ga and by variable elution efficiencies obtained during the lifetime of the ^{68}Ge/^{68}Ga generator. Care was taken that all preparations contained 2 nmol PSMA ligand.

Fifteen patients were investigated with a BIOGRAPH-6 (Siemens). For those patients, an unenhanced CT scan was obtained 1 and 3 h after tracer injection using the following parameters: slice thickness, 5 mm; increment, 0.8 mm; soft-tissue reconstruction kernel; 130 keV
FIGURE 1. Maximum-intensity projections of patient 4 with normal distribution of ^{68}Ga-PSMA-617 at 3 h after injection. Physiologic accumulation is seen in lacrimal and salivary glands, nasal mucosa, liver, spleen, bowels, and kidneys. Surplus tracer is excreted via urinary tract and urinary bladder. No pathologic tracer uptake was found.

and 80 mAs. Immediately after CT scanning, whole-body PET was performed in 3-dimensional mode (matrix, 164 × 164). For each bed position (16.2 cm; overlapping scale, 4.2 cm), a 4-min acquisition time with a 15.5-cm field of view was used. The emission data were corrected for random, scatter, and decay events. Reconstruction was conducted with an ordered-subset expectation maximization algorithm with 2 iterations and 8 subsets and Gauss-filtered to a transaxial resolution of 5 mm in full width at half maximum. Attenuation correction was performed using the low-dose unenhanced CT data.

Image analysis was performed using an appropriate workstation and software (Syngo TrueD; Siemens).

For the 4 patients who were scanned at 6 different times, we used a BIOGRAPH-mCT PET/CT scanner (Siemens). An unenhanced CT scan was obtained at 5 min, 1 h, 2 h, 3 h, 4 h, and 5 h after injection using the following parameters: slice thickness, 5 mm; increment, 2 mm; soft-tissue reconstruction kernel; 120 keV/60 mAs at 3 h after injection and 80 keV/30 mAs at 5 min, 1 h, 2 h, 4 h, and 5 h after injection. Immediately after CT scanning, whole-body PET was performed in 3-dimensional mode (matrix, 200 × 200). Each bed position (axial field of view, 16.2 cm) was acquired for 3 min. The emission data were corrected for random, scatter, and decay events. Reconstruction was conducted with an ordered-subset expectation maximization algorithm with 2 iterations and 8 subsets and Gauss-filtered to a transaxial resolution of 2 mm in full width at half maximum. Attenuation correction was performed using the low-dose unenhanced CT data.

The 2 different PET/CT scanners (BIOGRAPH-6 and BIOGRAPH-mCT) were cross-calibrated.

Image Evaluation

Two board-certified specialists in nuclear medicine with 10 and 27 y of clinical experience interpreted all datasets independently and resolved any disagreement by consensus.

The mean and maximum standardized uptake values (SUV_{mean} and SUV_{max}, respectively) of lacrimal, parotid, submandibular, and sublingual glands; mediastinal blood pool (aortic arch); and liver, spleen, small proximal bowel, colon, kidneys, and gluteal musculature (as background) were analyzed at 1 and 3 h after injection in 15 patients. In 4 patients, the same procedure was additionally conducted at 5 min, 2 h, 4 h, and 5 h after injection.

With regard to the colon, SUV was measured at the localization with the highest radiotracer uptake, which was usually the descending part.

For calculation of the SUV, circular regions of interest were drawn around areas with focally increased uptake in transaxial slices and automatically adapted to a 3-dimensional volume of interest (VOI) at a 70% isocontour.

SUVs in images acquired at 3 h after injection were compared with those at 1 h after injection and defined as increasing, decreasing, or stable, with intensity changes of greater than 10%, less than −10%, or between −10% and +10%, respectively.

Lesions that were visually considered as suggestive for PCa were counted and analyzed with respect to their localization (local relapses, lymph node [LN], bone, and soft-tissue metastases) and to their SUV_{mean} and SUV_{max}.

Any visible PCa lesion of a patient was counted and analyzed unless patients had more than 10 lesions. In such a case, a maximum of 10 lesions was analyzed after random selection. This kind of selection avoids an overestimation of SUVs because otherwise-dominant lesions would be preferentially selected.

Tumor contrast was measured by dividing the SUV_{mean} of tumor lesions by the SUV_{mean} of the background (gluteal musculature) and by dividing the SUV_{max} of tumor lesions by the SUV_{max} of the background.

Statistical Analysis

The statistical distribution of SUV_{mean} and SUV_{max} values was assessed visually and by Shapiro–Wilk tests and found to be approximately normal. Thus, SUVs of the above-mentioned organs and of the tumor lesions at 1 and 3 h after injection were compared using a paired-sample t test.

Because PSA levels showed a skewed distribution, a 2-sided Mann–Whitney test was used to evaluate differences concerning PSA values between groups with and without pathologic findings in PET/CT.

A P value of less than 0.05 was considered statistically significant.

Radiation Dosimetry

To find the optimal point of time for the diagnostic examination, the activity distribution of 4 patients was measured at 5 min, 1 h, 2 h, 3 h, 4 h, and 5 h after injection of ^{68}Ga-PSMA-617. The data of these patients were used to estimate the internal radiation dose.

The activity distributions of the source organs were determined with the help of PMOD software (PMOD Technologies), which was

FIGURE 2. Average SUV_{mean} and SUV_{max} in different organs 1 and 3 h after injection. Significance of differences between 1 and 3 h (t test): #$P < 0.001$; *$P < 0.05$; ~$P > 0.05$. Gl. = glandular; Glut. Musc. = gluteal musculature.
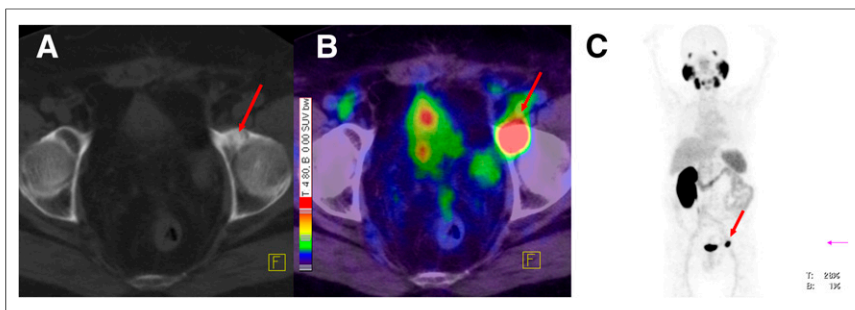

FIGURE 3. (A–C) ^{68}Ga-PSMA-617 PET/CT of patient 11 at 1 h after injection. Red arrows point to a bone metastasis with SUV$_{max}$ of 21.7 at 1 h and 32.6 at 3 h after injection. (A) Low dose CT. (B) Fusion of PET and CT. (C) MIP of PET/CT. MIP = maximum-intensity projection.

used to define the VOIs in the PET images. The VOIs were chosen in the way that the whole activity of the organ was considered. Care needed to be taken to not interfere with the activity concentration of adjacent organs. The number of disintegrations in the organs divided by administered activity was estimated by integration of the time–activity curves of the corresponding VOIs. This is the area under the time–activity curve normalized to the amount of activity administered and is termed residence time in the following sections as it is an established term in internal dosimetry.

After the residence times of the source organs were calculated, the organ doses and the effective dose per unit of administered activity were calculated using the OLINDA/EXM application (version 1.1) (26).

The urinary excretion was also considered. The patients were asked to collect the excreted urine before each PET/CT measurement. The activity of the urine was determined separately. This activity was

FIGURE 4. ^{68}Ga-PSMA-617-PET/CT of patient 3 at 1 h (C and D) and 3 h after injection (A and B). Red arrows point to LN (Virchow's node), which was identified as metastasis in images at 3 h after injection only. In images at 1 h after injection, tracer accumulation was rated as artifact. In this patient, also 4 other LNs (retroperitoneal) were identified as metastases in images at 3 h after injection only. (A) Fusion of PET and CT 3 h after injection. (B) Maximum-intensity projection of PET/CT 3 h after injection. (C) Fusion of PET and CT 1 h after injection. (D) Maximum-intensity projection of PET/CT 1 h after injection.

added to the urinary bladder content calculated from the PET/CT measurements. The excreted activity (decay corrected) was subtracted from the remainder measured at the next PET/CT measurement.

RESULTS

None of the patients developed adverse events or clinically detectable pharmacologic effects. Figure 1 demonstrates the maximum-intensity projection of a patient with normal biodistribution of ^{68}Ga-PSMA-617 at 3 h after injection.

Average SUV$_{mean}$ and SUV$_{max}$ values of different tissues in all patients analyzed (1 and 3 h after injection) are summarized in Figure 2 and Supplemental Table 1 (supplemental materials are available at http://jnm. snmjournals.org). Intraindividual changes in SUVs between 1 and 3 h after injection (increase, decrease, and stable) were investigated in all patients. The most reproducible trend was registered in the spleen, with almost all patients showing a decrease in radiotracer uptake.

A statistically significant increase of SUV$_{mean}$ at 3 h after injection was observed in the following organs: lacrimal glands (+19.5%; $P < 0.001$), nasal mucosa (+19.2%; $P = 0.011$), parotid glands (+25.2%; $P < 0.001$), submandibular glands (+24.2%; $P < 0.001$), proximal small intestine (+18.4%; $P = 0.003$), and colon (+13.0%; $P = 0.040$). SUV$_{mean}$ also increased in the sublingual glands (+7.9%; $P = 0.066$) and kidneys (+9.9%; $P = 0.072$), however, without statistical significance.

A statistically significant decrease of SUV$_{mean}$ between 1 and 3 h after injection was observed in the mediastinal blood pool (−5.6%; $P = 0.041$) and liver (−18.6%; $P < 0.001$). SUV$_{mean}$ decreased also in the gluteal musculature (−0.8%; $P = 0.826$), however, without being statistically significant.

A statistically significant increase of SUV$_{max}$ was detected in lacrimal glands (+34.5%; $P = 0.001$), nasal mucosa (+27%; $P = 0.003$), parotid glands (+32.1%; $P < 0.001$), submandibular glands (+31.3%; $P < 0.001$), sublingual glands (+19.4%; $P < 0.001$), proximal small intestine (+33.4%; $P < 0.001$), colon (+27.3%; $P = 0.003$), and kidneys (+17.0%; $P = 0.002$). An increase was also observed in the liver (+7.3%; $P = 0.090$), without reaching statistical significance.

A statistically significant decrease of SUV$_{max}$ between 1 and 3 h after injection was observed in the mediastinal blood pool (−12.9%; $P = 0.001$) and spleen (−11.5%; $P = 0.001$). SUV$_{max}$ decreased also in the gluteal musculature (−6.3%; $P = 0.331$), however, without being statistically significant.

In 14 of 19 patients (73.7%), at least 1 lesion suspected of being a tumor was detected. Figures 3 and 4 and Supplemental Figures 1 and 2 show some representative PCa lesions. Among all lesions visually considered typical for PCa, we selected 53 representative lesions for further analysis (Fig. 5). Of these, 39 were defined as LN metastases (in 8 different patients), 8 as bone metastases (in 2 different patients), 3 as local relapses (in 3 different patients), and 3 as primary tumors (in 2 different patients).

As demonstrated by Figure 5 and Supplemental Figure 3, SUV$_{mean}$ and SUV$_{max}$ increased in 46 and 50 lesions, respectively; decreased in 3 and 2 lesions, respectively; and remained stable in 4 and 1 lesions, respectively, between 1 and 3 h after injection. In patient 3, 5 of overall 8 lesions (Fig. 5, lesions 11, 12, 14, 17, and
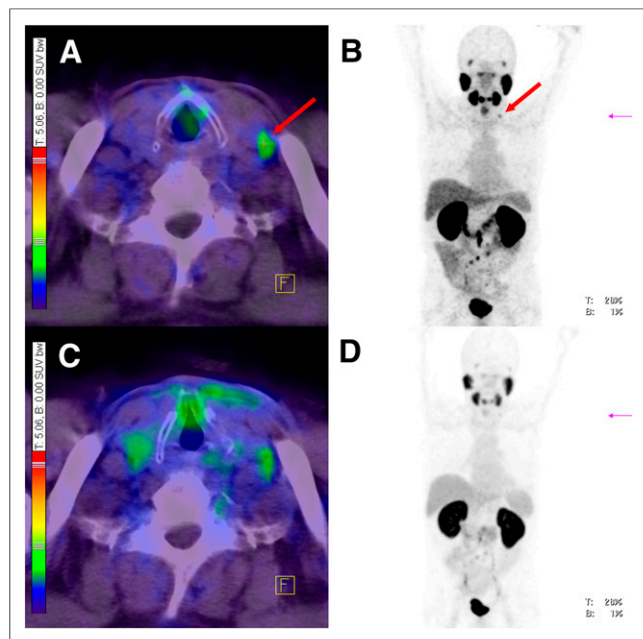

FIGURE 5. Average SUV$_{max}$ in 53 representative PCa lesions and their ratio to background (contrast) 1 and 3 h after injection. Five of overall 8 lesions (lesions 11, 12, 14, 17, and 18) in patient 3 and 1 of overall 2 lesions (lesion 31) patient 16 were not visible in images at 1 h after injection because of low contrast.

Patients without pathologic findings ($n = 5$) had a mean PSA of 0.5 ± 0.5 ng/mL (range, 0.1–1.3 ng/mL; median, 0.4 ng/mL) and a median Gleason score of 7.0 (range, 7–8) and were injected with a mean of 189 ± 71 MBq of radiotracer (range, 68–255 MBq; median, 237 MBq).

Patients with pathologic findings ($n = 14$) had a mean PSA of 7.3 ± 6.6 ng/mL (range, 1.3–24.3 ng/mL) and a median Gleason score of 7 (range, 5–9) and were injected with a mean of 196.8 ± 54 MBq of radiotracer (range, 132–295 MBq).

There was no significant difference in Gleason score and injected amount of tracer (activity, measured in MBq) between both groups (with/without pathologic findings in PET/CT). However, PSA levels were significantly lower ($P = 0.002$) in the group without pathologic findings in the ^{68}Ga-PSMA-617 PET/CT.

Follow-up information was available for 10 patients. Among these, 6 received local treatment: 5 were treated with external radiation of PSMA-positive lesions (all of them demonstrated a decrease of PSA) and 1 was operated on (presented with a decrease of PSA thereafter). Two patients were treated by androgen-deprivation therapy only, and 2 others did not receive any treatment after PET/CT.

18) and in patient 16, 1 of overall 2 lesions (Fig. 5, lesion 31) were not visible in the images at 1 h after injection because of low contrast.

The detailed SUVs of different types of PCa lesions at 1 and 3 h after injection are listed in Table 2. The highest SUVs were measured in bone metastases, followed by LN metastases, local relapses, and primary tumors.

The effective dose of ^{68}Ga-PSMA-617 was determined in 4 patients. An average activity of 231 MBq was injected intravenously. Figure 6 presents the uptake and contrast of all tumor lesions in relation to the different times after the injection of

TABLE 2

PSMA-617. As visible, most PCa lesions show an increase of uptake and contrast by time. Representatively, Figure 7 demonstrates maximum-intensity projections of a sequential PET/CT scan of patient 18 and the corresponding SUV_{max} of 2 primary PCa lesions.

Table 3 provides the estimated residence times of ^{68}Ga of the selected source organs. The estimated organ doses in Table 4 show that the kidneys and the urinary bladder wall were the organs with the highest dose. As presented also by Table 4, the effective doses for patients 16–19 were 0.021 mSv/MBq $\pm$ 15% (maximum deviation), leading to an effective dose of 4.3 mSv for an injected activity of 203 MBq (mean injected activity of the 19 patients).

Supplemental Figures 4 and 5 show the decay-corrected radioactivity in the source organs as a function of time. The remainder was in the range of 65%–75% whereas the source organ distributions were of the order of magnitude of 15%. The major contribution resulted from the kidneys, urinary bladder, and liver. The small intestine, upper large intestine, and spleen have been
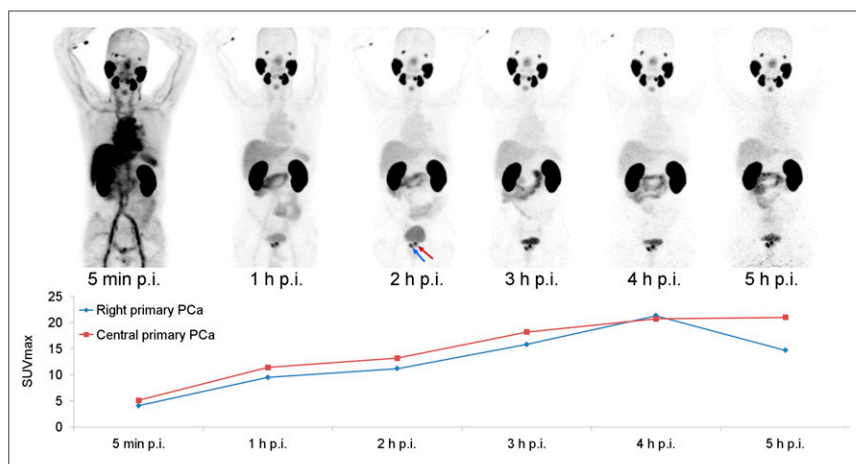

additionally considered as minor radiotracer uptake, with a mostly constant time course.

The activity of the lacrimal and salivary glands was below 2% of the injected activity and was considered in the remainder.

This approach has no effect for the estimation of the effective dose. When PSMA-617 is used with radioligand therapy, the organ doses of lacrimal and salivary glands should be considered individually.

DISCUSSION

The clinical introduction of PET imaging with the PSMA ligand ^{68}Ga-PSMA-11 has been regarded as a significant improvement in the diagnosis of PCa. The hitherto existing results are highly promising and demonstrate that PSMA ligand PET/CT could be superior to other modalities for the diagnosis of recurrent PCa (19–23). However, more recently, ^{68}Ga-PSMA-11 has been structurally modified with the goal to allow labeling with several radiometals such as ^{68}Ga, ^{111}In, ^{177}Lu, and ^{90}Y (24). ^{177}Lu-labeled PSMA-617 is already in use for the treatment of metastatic PCa in multiple centers (25). So far, the performance of this novel PSMA ligand in the diagnosis of PCa in humans has not yet been evaluated. To assess the applicability of tumor imaging with ^{68}Ga-PSMA-617, we evaluated the distribution of this theranostic substance in normal tissues, determined the radiotracer uptake in PCa lesions, and analyzed the radiation exposure of ^{68}Ga-PSMA-617 PET.

PSMA expression and uptake of radiolabeled PSMA ligands, mostly at low levels, has been reported for various normal tissues (21,27–29). In agreement with these data, our analysis demonstrated significant PSMA-617 uptake in the salivary glands and kidneys and to a lesser extent in lacrimal glands, liver, spleen, and bowel as well. In addition, the salivary and lacrimal glands showed a slight increment of radiotracer uptake between early and late images. This uptake is suggestive of radiotracer trapping and has already been shown as contributing to side effects during treatment with radiolabeled PSMA ligands (28). However, in most other organs our data demonstrate relatively stable uptake values between early and late images at levels similar to ^{68}Ga-PSMA-11, with the exception of the kidneys. The PSMA-617 uptake of the kidneys is significantly lower than ^{68}Ga-PSMA-11. Our observation is in accordance with preclinical studies in which a relatively low uptake and a fast clearance of the kidneys could be demonstrated: 113 percentage injected dose per gram at 1 h to 2.13 percentage injected dose at 24 h (24). This lower uptake and faster clearance result in a lower radiation exposure to the kidneys with consecutive advantages for patients who are referred to a PSMA-based radioligand therapy of metastatic PCa.

In addition, it might be hypothesized that the use of the same substance for both therapy and diagnosis can be a further advantage as it maximizes the precision of therapy response evaluation.

Among normal tissues, SUV decreased in the liver and spleen. Because PSMA expression is reported to be low in these organs (27), we hypothesized that radioactivity measured in these tissues partially reflects a blood-pool effect and is washed

Blue and red arrows point to 2 primary PCa lesions. (Lower) SUV_{max} of the 2 primary PCa lesions at the different times. p.i. = after injection.

TABLE 3
Dosimetry Data and Residence Times of ^{68}Ga-PSMA-617

	Residence time (Bq × h/Bq) for patient			
Source organ	16	17	18	19
Liver	0.110	0.068	0.102	0.090
Spleen	0.014	0.006	0.003	0.013
Kidneys	0.153	0.053	0.196	0.125
Urinary bladder	0.076	0.095	0.045	0.059
Small intestine	0.011	0.002	0.018	0.004
Colon	0.042	0.033	0.052	0.004
Remainder	1.190	1.320	1.190	1.290

out as a result of the plasma clearance of the radiotracer. We cannot exclude that the ^{68}Ga-labeled PSMA ligand as a small molecule redistributes from the intravascular compartment to the interstitial space with time, though.

In the preclinical literature, PSMA expression has been described for the proximal small intestine (27,30). However, in agreement with our experiences with PSMA-11, all of our patients additionally showed PSMA-617 uptake in parts of the colon as well. We suggest that uptake in the colon reflects PSMA expression in neuroendocrine cell populations of colonic crypts or physiologic regeneration areas (27). In our study, there was no evidence of radiotracer clearance via the biliary tract. Furthermore, visualization of the gallbladder was not observed.

Radiotracer detection in nasal mucosa could be explained either by PSMA expression in areas of tissue regeneration or by a blood-pool effect.

Within all tumor lesions, bone metastases presented with the highest SUVs, followed by LN metastases, local relapses, and primary tumors. These results have to be interpreted with caution, though, as the number of lesion types is low and as there is a bias with regard to the number of lesions detected in the different patients. Larger studies are necessary to show which type of lesions present with the highest uptake of PSMA-617. However, our analysis of PSMA-11 uptake in 319 patients showed no significant difference of uptake in bone metastases ($n = 359$) and LN metastases ($n = 328$) (22).

Our study demonstrates that PCa lesions usually present with sufficient contrast already 1 h after the injection of ^{68}Ga-PSMA-617. However, images at 3 h after injection showed approximately 90% of the PCa lesions with significantly improved tracer uptake (SUVs) and contrast. This higher uptake and contrast resulted in the detection of 6 additional PCa lesions at 3 h after injection, compared with images at 1 h after injection (5 lesions in 1 patient and 1 lesion in another patient). Although these additional lesions did not change the tumor stage of the patients, we suggest obtaining images at times later than 1 h after injection. The increase of PSMA ligand uptake and tumor contrast by time have not only been demonstrated by the dosimetry data of this current study but also by our experiences with ^{177}Lu-PSMA-617 in the radioligand therapy of metastatic PCa (unpublished data of our institute, collected since 2011).

In addition, our previous analysis with PSMA-11 pointed out that most PCa lesions present with higher uptake and contrast in images obtained at 3 h after injection than at 1 h after injection. The higher uptake and contrast were observed in approximately 70% of the lesions (compared with ~90% when using PSMA-617). In addition, all 65 lesions in all 37 patients of our previous study with ^{68}Ga-PSMA-11 detected at 3 h after injection were already visible at 1 h after injection (21). That is to say, for ^{68}Ga-PSMA-11 obtaining images at 1 h after injection seems to be sufficient.

The above-mentioned results indicate that PSMA-617 presents with slower pharmacokinetics. Also considering the SUVs in Figure 6, we suggest performing PET/CT at 2–3 h after injection of ^{68}Ga-PSMA-617. Images later than 3 h after injection can help to clarify unclear lesions because still many tumor lesions show increasing uptake and contrast at later times (Fig. 6). In this context, radionuclides with longer half-life, for example, ^{18}F, could show some advantages in imaging when used as a radiofluorinated PSMA-617 analog. On the other hand, a fast clearance of the radiolabeled molecule allows early imaging and does not need radionuclides with longer physical half-life. However, when using radiofluorinated PSMA ligands, a ^{68}Ga infrastructure does not need to be set up. In addition, the availability of cyclotron-based ^{18}F is significantly higher than the generator-based ^{68}Ga. Most recently, the team of Martin Pomper introduced an ^{18}F-labeled PSMA ligand, ^{18}F-DCFPyL (14).

Few PCa lesions decreased in SUV and contrast in later images (Fig. 5). Although the reason remains unclear, we speculate that some tumors show a reduced internalization rate of the PSMA ligand. Further studies are mandatory to clarify this observation.

PSMA-negative prostate carcinoma seems to be rare (31,32). Consequently, the question remains why more patients do not present with a pathologic PET/CT in our retrospective analysis. Low or even absent PSMA expression and small tumor lesions could be sufficient explanations as to why not every patient of our collective presented with a pathologic 68Ga-PSMA-617 PET/CT finding.

The question remains which 68Ga-labeled version of PSMA-targeted radioligand, 68Ga-PSMA-11 or 68Ga-PSMA-617, can be more recommended for diagnosing PCa. Usually the clinical routine is designed to conduct different PET scans at 1 h after injection only (e.g., 18F-FDG, DOTA conjugates, PSMA-11, 18F-DOPA). In this context, patients with multiple scans and later images require complex planning as they otherwise would disturb the clinical routine. Therefore, PSMA-11 with its putatively faster clearance provides a clear advantage. It remains unclear if PSMA-617, with its higher binding affinity and internalization, could detect more PCa lesions in a reasonable time window after injection than PSMA-11. Because of the same molecular effects, we believe that both PSMA ligands show also the same specificity for PCa. Overall, a study with a direct intraindvidual comparison between both ligands is mandatory to clarify which ligand is superior. Besides all mentioned considerations, we believe that centers that integrate 68Ga-PSMA-617 into their clinical routine will be able to provide an excellent tool to diagnose PCa with vast scientific possibilities.

One limitation of our presented analysis is the lack of systematic histopathologic investigations of PET-positive lesions. However, since 68Ga-PSMA ligand PET/CT was introduced, the available data indicate that any uptake of PSMA ligands above local background in CT-morphologic-visible lesions is highly specific for PCa and, thus, has to be regarded as PCa unless otherwise proven. In this context, none of the lesions examined for this analysis was unclear: they all were typical for PCa. This statement is also supported by the results of the follow-up: patients who received targeted radiation therapy or lymphadenectomy of PET-positive lesions after the PET/CT all presented with a decrease of PSA.

With regard to the dosimetry analysis, most of the injected activity could be considered to be homogeneously distributed in the remainder. The highest activity accumulation was found in the urinary bladder, the kidneys, and the small intestine. An average effective dose of 0.021 mSv/MBq was estimated. For instance, a low-dose 68Ga-PSMA-617 PET/CT with an administered activity of 203 MBq results in an effective overall dose of 4.3 mSv (PET) + 3.5 mSv (low-dose CT), which equals 7.8 mSv. These results are similar compared with other most recently introduced PSMA ligands (14,33).

CONCLUSION

This analysis presents the biodistribution and tumor uptake of 68Ga-PSMA-617 in patients. Within healthy organs, kidneys and salivary glands demonstrated the highest radiotracer uptake whereas lacrimal glands, liver, spleen, and bowel showed relatively moderate uptake. 68Ga-PSMA-617 shows lesions of PCa with high contrast, especially in late images. Maximum contrast of tumor lesions is usually seen between 3 and 4 h after injection. The radiation exposure of a PET scan with 68Ga-PSMA-617 is approximately 0.021 mSv/MBq.
