Risk factors for cerebrovascular complications developing during or after carotid endarterectomy (CEA) include preoperative impairments in cerebral hemodynamics, as detected by the demonstration of decreased cerebrovascular reactivity (CVR) to acetazolamide on brain perfusion SPECT. Central benzodiazepine receptor binding potential (CBRBP) and cerebral blood flow (CBF) images on SPECT provide high sensitivity and high specificity for detecting misery perfusion in patients with chronic unilateral major cerebral artery occlusive disease. The aim of the present study was to determine whether preoperative CBRBP/CBF images on SPECT could identify patients at risk for new cerebral ischemic events, including neurologic deficits and cerebral ischemic lesions on diffusion-weighted MRI, or cerebral hyperperfusion after CEA and to compare the predictive accuracy of CBRBP/CBF with that of CVR to acetazolamide on SPECT. **Methods:** CBF, CVR, and CBRBP were assessed using *N*-isopropyl-*p*-¹²³I-iodoamphetamine (¹²³I-IMP) and ¹²³I-iomazenil SPECT before CEA in 112 patients with unilateral internal carotid artery stenosis ($\geq 70\%$). CBF measurement using ¹²³I-IMP SPECT was also performed immediately and 3 d after CEA. A region of interest was automatically placed in the middle cerebral artery territory in both cerebral hemispheres using a 3-dimensional stereotactic region-of-interest template. Diffusion-weighted MRI was performed within 3 d before and 24 h after surgery. **Results:** A preoperative increase in the affected side-to-contralateral side asymmetry on CBRBP/CBF value was the only significant independent predictor of postoperative new cerebral ischemic events (95% confidence intervals [CI], 1.145–1.608; $P = 0.0004$) or post-CEA hyperperfusion (95% CI, 1.244–2.252; $P = 0.0007$). There was no difference in the ability to predict post-CEA hyperperfusion when comparing the area under the receiver-operating-characteristic curve of the affected side-to-contralateral side asymmetry on CBRBP/CBF and that of the CVR in the affected hemisphere. However, the former value (0.924; 95% CI, 0.854–0.972) was significantly greater than the latter value (0.782; 95% CI, 0.697–0.852) for the prediction

of new postoperative cerebral ischemic events ($P < 0.05$). **Conclusion:** Preoperative CBRBP/CBF images on SPECT can more accurately identify patients at risk for cerebrovascular complications occurring during or after CEA when compared with preoperative CVR to acetazolamide.

DOI: 10.2967/jnumed.111.087940

Neurologic deficits after carotid endarterectomy (CEA) are rare, occurring in up to 5% of patients (1–3). Hemodynamic cerebral ischemia due to hemispheric hypoperfusion during internal carotid artery (ICA) clamping and the generation of emboli from the surgical site play significant roles in the development of new cerebral ischemic events, including new neurologic deficits and new cerebral ischemic lesions on diffusion-weighted MRI (DWI) after CEA (4–11). Cerebral hyperperfusion syndrome is also a complication after CEA and is characterized by unilateral headache, face and eye pain, seizure, and focal symptoms that occur secondary to cerebral edema or intracerebral hemorrhage (12–15). In addition, recent studies have demonstrated that post-CEA hyperperfusion, even when asymptomatic, causes postoperative cortical neural damage that results in postoperative cognitive impairment (16–18).

Risk factors for the development of cerebrovascular complications associated with CEA include preoperative impairments in cerebral hemodynamics (19–24). Several investigators have demonstrated that a decrease in cerebrovascular reactivity (CVR) to acetazolamide, as measured using SPECT, predicts postoperative new cerebral ischemic events due to hemispheric hypoperfusion during ICA clamping (19) or emboli from the surgical site (20), or post-CEA hyperperfusion (22–24). However, acetazolamide is associated with frequent and various adverse side effects, including metabolic acidosis, hypokalemia, numbness of the

extremities, headache, tinnitus, gastrointestinal disturbances, and Stevens–Johnson syndrome (25,26). In fact, 1 study demonstrated that 63% of patients who underwent a SPECT study with acetazolamide challenge developed adverse effects between 1 and 3 h after administration of acetazolamide, and these symptoms lasted for 0.5–72 h (27) and frequently affected patients' activities of daily living, including the ability to engage in their jobs (27). Thus, it would be beneficial to develop a different SPECT method of predicting the cerebrovascular complications associated with CEA that does not require administration of acetazolamide.

The distribution of central benzodiazepine receptors in the cerebral cortex of the human brain has been widely studied with SPECT using ^{123}I -iomazenil (^{123}I -IMZ) (28–31). Central benzodiazepine receptor binding potential (CBRBP) on ^{123}I -IMZ SPECT images is associated with neural density in the cerebral cortex, and a reduction in cortical CBRBP indicates cortical neural damage or loss (29–31). In the cerebral cortex with reduced CBRBP, cerebral metabolic rate of oxygen (CMRO_2) probably decreases in proportion to the degree of neuronal damage. In fact, CBRBP images on ^{123}I -IMZ SPECT reportedly correlate with CMRO_2 images on PET in the cerebral cortex in patients with carotid artery occlusive diseases (32,33). Because oxygen extraction fraction (OEF), one of the key parameters of cerebral hemodynamics (34,35), is a function of CMRO_2 and cerebral blood flow (CBF), CBRBP/CBF may reflect OEF. Indeed, a recent study has demonstrated that CBRBP/CBF images on SPECT correlate with OEF images on PET and provide high sensitivity and high specificity for detecting misery perfusion in the cerebral cortex in patients with chronic unilateral major cerebral artery occlusive disease (33).

Therefore, the aim of the present study was to determine whether preoperative CBRBP/CBF images on SPECT could identify patients at risk for new cerebral ischemic events or cerebral hyperperfusion after CEA and to compare the predictive accuracy of CBRBP/CBF with that of CVR to acetazolamide on SPECT.

MATERIALS AND METHODS

Patients

One hundred twelve patients (105 men and 7 women), aged 44–82 y (mean age, 69 y), with unilateral ICA stenosis ($\geq 70\%$) and useful residual function (modified Rankin disability scale 0, 1, or 2) who underwent CEA were enrolled in the present study. Concomitant disease states and symptoms were recorded, including 102 patients with hypertension, 42 patients with diabetes mellitus, and 61 patients with hyperlipidemia. Although 75 patients showed ischemic symptoms in the ipsilateral carotid territory, 37 patients exhibited asymptomatic ICA stenosis.

All patients underwent preoperative angiography with arterial catheterization. The overall average degree of ICA stenosis was $87.5\% \pm 8.3\%$, with a range of 70%–99%, as per the North American Symptomatic Carotid Endarterectomy Trial (3). No patient had occlusion or stenosis of greater than 50% in the contralateral ICA or middle cerebral artery (MCA).

This protocol was reviewed and approved by the institutional ethics committee, and written informed consent was obtained from all patients or their next of kin.

Brain SPECT Study

Brain SPECT studies were performed using a ring-type SPECT scanner (Headtome-SET080; Shimadzu Corp.) (33,36), which provided 31 tomographic images simultaneously. The spatial resolution of the scanner with a low-energy, all-purpose collimator was 13 mm in full width at half maximum at the center of the field of view, and the slice thickness was 25 mm in full width at half maximum at the center of the field of view. Image slices were taken at 5-mm center-to-center spacing, parallel to the orbitomeatal line. The images were reconstructed using the weighted-filtered backprojection technique, in which the attenuation correction was made by detecting the edge of the object. An attenuation coefficient of 0.065 cm^{-1} , a Butterworth filter (cutoff, 0.45 cycle/cm; order, 3), and a ramp filter were used for image reconstruction.

CBF was assessed using *N*-isopropyl- p - ^{123}I -iodoamphetamine (^{123}I -IMP) and SPECT 7–10 d before and immediately after CEA. The ^{123}I -IMP SPECT study with and without acetazolamide challenge was performed as described previously (36). Preoperatively, 3 d after measurement of CBF without acetazolamide challenge, subjects underwent SPECT with acetazolamide challenge. In addition, patients with post-CEA hyperperfusion underwent a third CBF measurement in the same manner 3 d after CEA. The CBF images were calculated according to the ^{123}I -IMP autoradiography method (36,37).

The distribution of CBRBP in the cerebral cortex was assessed using ^{123}I -IMZ SPECT between 2 and 7 d after ^{123}I -IMP SPECT study with acetazolamide challenge. Subjects received approximately 167 MBq of ^{123}I -IMZ by intravenous bolus injection of 1.5 mL of solution into the cubital vein. One hundred eighty minutes later, scans were initiated, with a scanning duration of 23 min (33).

All SPECT images were transformed into the standard brain size and shape by linear and nonlinear transformation using SPM99 for anatomic standardization (38). Thus, brain images from all subjects had the same anatomic format. For each pixel in SPECT images obtained before surgery, 2 values were calculated as follows: CBRBP/CBF (count/mL/100 g brain/min) = radioactive counts of ^{123}I -IMZ/CBF without acetazolamide challenge and $\text{CVR}(\%) = ([\text{CBF with acetazolamide challenge} - \text{CBF without acetazolamide challenge}]/\text{CBF without acetazolamide challenge}) \times 100$. Then, in all CBF, CBRBP/CBF, and CVR SPECT images, 318 constant regions of interest (ROIs) were automatically placed in both the cerebral and cerebellar hemispheres using a 3-dimensional stereotactic ROI template (39). The ROIs were grouped into 10 segments (callosomarginal, pericallosal, precentral, central, parietal, angular, temporal, posterior, hippocampus, and cerebellum) in each hemisphere according to the arterial supply. Five (precentral, central, parietal, angular, and temporal) of these 10 segments were combined and defined as an ROI perfused by the MCA (Fig. 1). The mean value of all pixels in the MCA ROI in each hemisphere was calculated.

Further, in preoperative CBRBP/CBF images of each patient, the asymmetry index (AI) was calculated as follows: $\text{AI} = (\text{CBRBP}/\text{CBF}_{\text{CEA}})/(\text{CBRBP}/\text{CBF}_{\text{CON}}) \times 100$, where $\text{CBRBP}/\text{CBF}_{\text{CEA}}$ is the value of the MCA ROI in the cerebral hemisphere ipsilateral to CEA, and $\text{CBRBP}/\text{CBF}_{\text{CON}}$ is that in the contralateral cerebral hemisphere. Using the same method, we studied 10 healthy subjects (8 men and 2 women; age, 35–

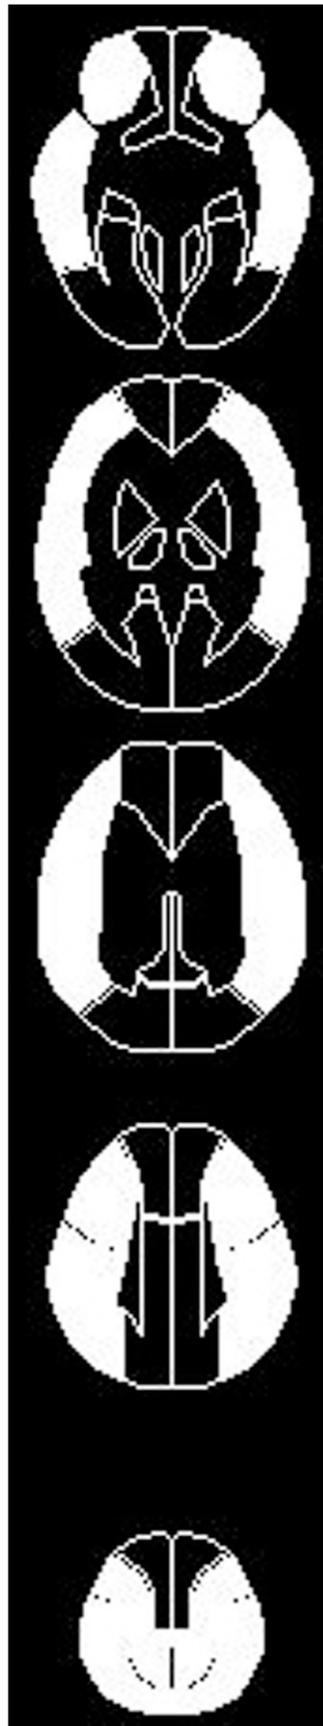

FIGURE 1. Diagrams showing ROIs of 3-dimensional stereotactic ROI template. White ROIs (precentral, central, parietal, angular, and temporal segments) indicate territories perfused by bilateral MCAs.

52 y; mean age, 39 y) to obtain control values. The control value of CBRBP/CBF AI was 100.1 ± 5.0 when the left cerebral hemisphere was defined as the affected side (33).

For CVR in the MCA ROI in the cerebral hemisphere ipsilateral to CEA, data described previously ($36.8\% \pm 9.2\%$) (20) were used as control values.

In CBF images of each patient, post-CEA hyperperfusion, compared with preoperative values in an MCA ROI ipsilateral to surgery, was defined as a CBF increase of 100% or more (i.e., a doubling) (23).

DWI

DWI was performed using a 1.5-T whole-body imaging system (Signa MR/I; GE Healthcare) within 3 d before and 24 h after surgery. The images were acquired using single-shot spin-echo echo-planar imaging.

A neuroradiologist who was unaware of the patients' clinical information was used to analyze the images and determine development of new postoperative ischemic lesions.

Assessment of Neurologic Deficits

All patients were neurologically tested immediately before induction of general anesthesia and after recovery from general anesthesia by a neurologist who was unaware of the patients' clinical information, and the presence or absence of new postoperative neurologic deficits was recorded.

Intraoperative and Postoperative Management

All patients received antiplatelet therapy until the morning of the day on which CEA was performed. Further, all patients underwent surgery under general anesthesia. Blood pressure was kept stable in a range $\pm 20\%$ of the preoperative level throughout the procedure by adjusting the depth of anesthesia or, if needed, by intravenous administration of a vasodilator (nitroglycerin) or a vasoconstrictor (theoadrenalin). An intraluminal shunt was not used in these procedures. The mean duration of ICA clamping was 36 min, ranging from 21 to 48 min. In all patients with post-CEA hyperperfusion, intensive control of arterial blood pressure between 100 and 140 mm Hg was instituted using intravenous administration of antihypertensive drugs immediately after SPECT. When CBF decreased and hyperperfusion resolved on the third postoperative day, pharmacologic control of blood pressure was discontinued. However, when hyperperfusion persisted, systolic arterial blood pressure was maintained below 140 mm Hg. When hyperperfusion syndrome developed, the patient was placed in propofol coma. A diagnosis of hyperperfusion syndrome required seizure, alteration in consciousness level, or focal neurologic signs such as motor weakness that developed or worsened between 24 h and 14 d after surgery, and hyperperfusion on the ^{123}I -IMP SPECT performed after CEA.

Statistical Analysis

Data are expressed as the mean \pm SD. The relationship between each variable and the development of new postoperative cerebral ischemic events (neurologic deficits or cerebral ischemic lesions on DWI) or post-CEA hyperperfusion was evaluated with univariate analysis using the Mann-Whitney U test or χ^2 test. A multivariate statistical analysis of factors related to the development of new postoperative cerebral ischemic events or post-CEA hyperperfusion was also performed using a logistic regression model. Variables with a P value of less than 0.2 in the univariate analyses were selected for analysis in the final model. However,

preoperative CVR in the affected hemisphere was not adopted in the model because previous studies have already established the strong relationship between this factor and the development of new postoperative cerebral ischemic events or post-CEA hyperperfusion (19,20,22–24). Differences were deemed statistically significant if the *P* value was less than 0.05. To estimate the ability to discriminate between patients with and without new postoperative cerebral ischemic events or post-CEA hyperperfusion, a receiver-operating-characteristic (ROC) curve was constructed, plotting sensitivity versus 1 minus specificity for possible cutoff values, and the area under the ROC curve was calculated. The ROC curve was calculated in increments or decrements of 0.5 SD (2.5 for CBRBP/CBF AI; 4.6% for CVR) from the mean value (100.1 for CBRBP/CBF AI; 36.8% for CVR) obtained in healthy subjects. Differences in the ROC area between the CBRBP/CBF AI and CVR in the affected hemisphere were analyzed using 95% confidence intervals (CIs).

RESULTS

Incidence and Course of Cerebrovascular Complications After CEA

Of the 112 patients studied, 9 patients (8%) developed new postoperative ischemic lesions on DWI in the cerebral hemisphere ipsilateral to CEA. All the new ischemic lesions were spotty and their diameters were 1.5 cm or less. Four patients (4%) developed new postoperative neurologic deficits: 2 (2%) with new postoperative cerebral ischemic lesions on DWI and 2 (2%) without. Although those deficits resolved completely within 12 h in 3 patients, the neurologic deficits in the remaining patient persisted for more than 24 h after surgery. Thus, a total of 11 patients (10%) experienced new postoperative ischemic events (postoperative cerebral ischemic lesions on DWI or postoperative neurologic deficits).

Thirteen patients (12%) met CBF criteria for post-CEA hyperperfusion on the CBF SPECT images obtained immediately after surgery. Of these 13 patients, 2 exhibited new transient neurologic deficits on recovery from general

anesthesia after surgery with (Fig. 2) or without new postoperative cerebral ischemic lesions on DWI, respectively.

In 11 of the 13 patients with hyperperfusion immediately after CEA, hyperperfusion was not present on the SPECT study performed on the third postoperative day, and these 11 patients had uneventful postoperative courses. However, the remaining 2 patients with cerebral hyperperfusion immediately after CEA experienced a progressive increase in CBF on the third postoperative day. Of these 2 patients, 1 who exhibited right transient hemiparesis on recovery from general anesthesia after surgery and who exhibited new postoperative cerebral ischemic lesions on DWI developed hyperperfusion syndrome with confusion and aphasia on the fourth postoperative day (Fig. 2). Another patient experienced cerebral hyperperfusion syndrome with confusion and right motor weakness with onset on the sixth postoperative day. Propofol coma was induced in both patients. After termination of the propofol coma, both patients eventually experienced full recovery.

Factors Related to New Postoperative Ischemic Events

Results of univariate analysis of factors related to the development of new postoperative ischemic events are summarized in Table 1. The preoperative CBRBP/CBF AI was significantly higher and the CVR in the affected hemisphere was significantly lower in patients with new postoperative ischemic events than in those without. Other variables were not significantly associated with the development of new postoperative ischemic events. After eliminating closely related variables in the univariate analyses, the following confounders (*P* < 0.2) were adopted in the logistic regression model for the multivariate analysis: sex, degree of ICA stenosis, and preoperative CBRBP/CBF AI. The multivariate analysis revealed that high preoperative CBRBP/CBF AI was significantly associated with the development of new postoperative ischemic events (95% CI, 1.145–1.608; *P* = 0.0004).

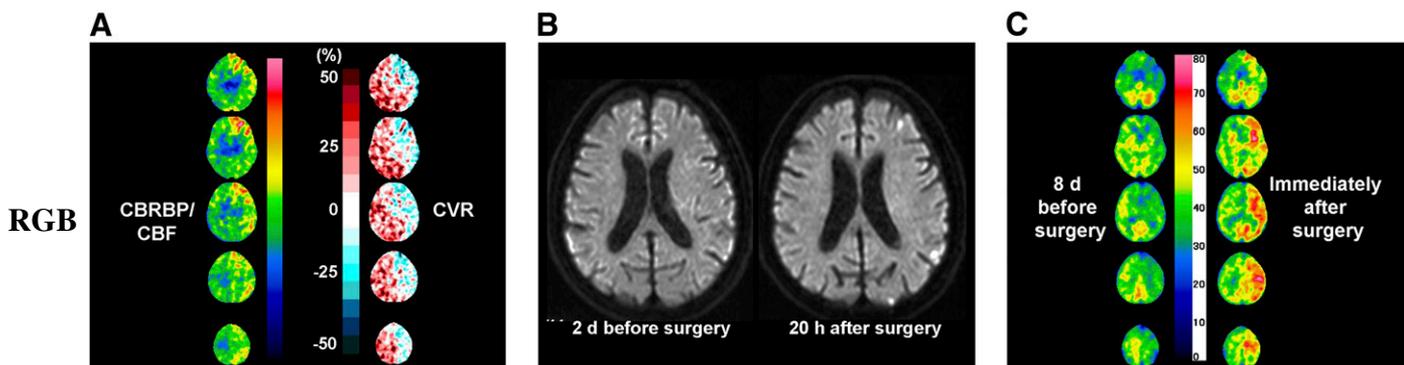

FIGURE 2. A 64-year-old man with symptomatic left internal carotid artery stenosis (95%) exhibiting slight right hemiparesis on recovery from general anesthesia after CEA. Six hours later, hemiparesis resolved. However, hyperperfusion syndrome with confusion and aphasia developed on fourth postoperative day. (A) Preoperative CBRBP/CBF and CVR to acetazolamide SPECT images show elevation of values in left cerebral cortex, compared with those in right cerebral cortex, and reduction of values in cerebral hemisphere, respectively. (B) Diffusion-weighted MR image before surgery shows no abnormal findings in left cerebral hemisphere, in which new multiple high intense lesions developed after surgery. (C) CBF SPECT images before surgery show hypoperfusion in left cerebral hemisphere, in which hyperperfusion developed immediately after surgery.

TABLE 1
Risk Factors for Development of New Postoperative Cerebral Ischemic Events

Risk factor	New postoperative cerebral ischemic events		P
	Yes (n = 11)	No (n = 101)	
Age (y)	71.2 ± 5.3	68.4 ± 6.8	0.2767
Male sex	9 (82)	96 (95)	0.1404
Hypertension	10 (91)	92 (91)	>0.9999
Diabetes mellitus	3 (27)	39 (39)	0.5318
Hyperlipidemia	6 (55)	55 (54)	>0.9999
Symptomatic lesions	9 (82)	66 (65)	0.3332
Degree of ICA stenosis (%)	89.5 ± 8.8	87.2 ± 8.3	0.1337
Duration of ICA clamping (min)	35.5 ± 6.4	36.2 ± 5.5	0.6915
Preoperative CBRBP/CBF AI	110.8 ± 6.6	102.1 ± 5.0	<0.0001
Preoperative CVR to acetazolamide (%)	13.6 ± 14.1	28.7 ± 11.8	0.0010

Data are mean ± SD, and data in parentheses are percentages.

Figure 3A illustrates the ROC curves of the CBRBP/CBF AI and the CVR to acetazolamide in the affected hemisphere, which can be taken as a measure of their ability to predict the development of new postoperative ischemic events. The ROC area of the CBRBP/CBF AI (0.924; 95% CI, 0.854–0.972) was significantly greater than that of the CVR (0.782; 95% CI, 0.697–0.852) ($P < 0.05$).

Sensitivity and specificity for the CBRBP/CBF AI in the cutoff point lying closest to the left upper corner of the ROC curve in predicting development of new postoperative ischemic events were 91% (10/11) and 73% (74/101) (cutoff point, 105.1: the mean + SD of the control value obtained from healthy subjects), respectively (Figs. 3A and 4). In the cutoff point, positive and negative predictive values were 27% (10/37) and 99% (74/75), respectively.

Subgroup analysis of patients with and without development of new neurologic deficits immediately after surgery, regardless of whether they developed new postoperative cerebral ischemic lesions on DWI, was performed in the same manner. Results of univariate analysis of factors related to the development of new postoperative neurologic deficits are summarized in Supplemental Table 1 (supplemental materials are available online only at <http://jnm.snmjournals.org>). The preoperative CBRBP/CBF AI was

significantly higher in patients with new postoperative neurologic deficits than in those without. Other variables, including CVR to acetazolamide, were not significantly associated with the development of new postoperative neurologic deficits. After eliminating closely related variables in the univariate analyses, the following confounders ($P < 0.2$) were adopted in the logistic regression model for the multivariate analysis: degree of ICA stenosis and preoperative CBRBP/CBF AI. The multivariate analysis revealed that high preoperative CBRBP/CBF AI was significantly associated with the development of new postoperative neurologic deficits (95% CI, 1.002–1.156; $P = 0.0477$).

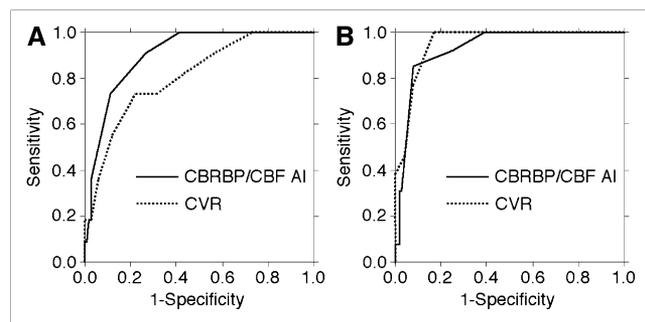

FIGURE 3. ROC curves used to determine accuracy of CBRBP/CBF AI and CVR to acetazolamide in prediction of new postoperative ischemic events (A) and postoperative hyperperfusion (B).

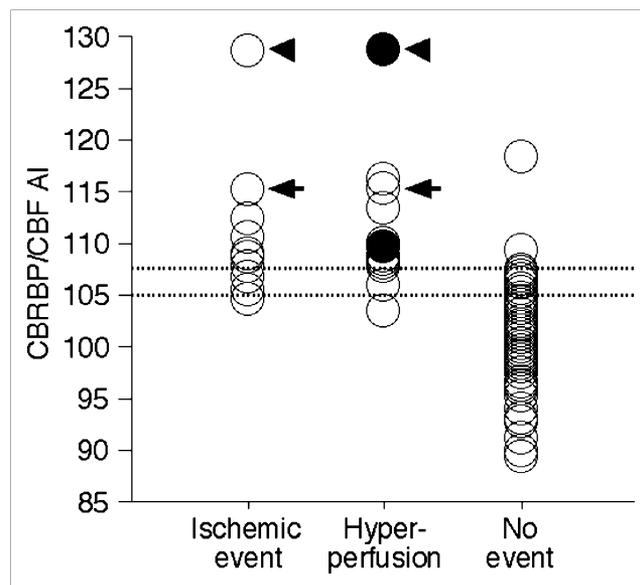

FIGURE 4. Relationship between CBRBP/CBF AI, postoperative ischemic events, and postoperative hyperperfusion. Arrows or arrowheads indicate identical patient with both postoperative ischemic events and postoperative hyperperfusion. Closed circles indicate patients with cerebral hyperperfusion syndrome. Each dashed horizontal line denotes mean + 1.5 (107.6) or mean + 1 (105.1) SD of CBRBP/CBF AI obtained in healthy volunteers, respectively.

Supplemental Figure 1 shows ROC curves of the CBRBP/CBF AI and the CVR to acetazolamide in the affected hemisphere, which can be taken as a measure of their ability to predict development of new postoperative neurologic deficits. The ROC area of the CBRBP/CBF AI (0.892; 95% CI, 0.815–0.941) was significantly greater than that of the CVR (0.737; 95% CI, 0.647–0.813) ($P < 0.05$).

Sensitivity and specificity for the CBRBP/CBF AI in the cutoff point lying closest to the left upper corner of the ROC curve in predicting development of new postoperative neurologic deficits were 100% (4/4) and 69% (75/108) (cutoff point, 105.1: the mean + SD of the control value obtained from healthy subjects), respectively (Supplemental Fig. 1). In the cutoff point, positive and negative predictive values were 11% (4/37) and 100% (75/75), respectively.

Factors Related to Post-CEA Hyperperfusion

Results of univariate analysis of factors related to the development of cerebral hyperperfusion after CEA are summarized in Table 2. The preoperative CBRBP/CBF AI was significantly higher and the CVR in the affected hemisphere was significantly lower in patients with post-CEA hyperperfusion than in those without. Other variables were not significantly associated with the development of post-CEA hyperperfusion. After closely related variables in the univariate analyses were eliminated, the following confounders ($P < 0.2$) were adopted in the logistic regression model for the multivariate analysis: symptomatic lesions, degree of ICA stenosis, and preoperative CBRBP/CBF AI. The multivariate analysis revealed that high preoperative CBRBP/CBF AI was significantly associated with the development of postoperative cerebral hyperperfusion (95% CI, 1.244–2.252; $P = 0.0007$).

Figure 3B illustrates ROC curves of the CBRBP/CBF AI and the CVR in the affected hemisphere, which can be taken as a measure of their ability to predict development of post-CEA hyperperfusion. There was no significant difference when comparing the ROC area of the CBRBP/CBF AI (0.925; 95% CI, 0.860–0.966) and that of the CVR (0.954; 95% CI, 0.897–0.985).

Sensitivity and specificity for the CBRBP/CBF AI in the cutoff point lying closest to the left upper corner of the ROC curve in predicting development of post-CEA hyperperfusion were 85% (11/13) and 92% (91/99) (cutoff point, 107.6: the mean + 1.5 SDs of the control value obtained from healthy subjects), respectively (Figs. 3B and 4). In the cutoff point, positive and negative predictive values were 58% (11/19) and 98% (91/93), respectively.

DISCUSSION

The present study demonstrated that preoperative CBRBP/CBF images on SPECT can more accurately identify patients at risk for cerebrovascular complications occurring during or after CEA when compared with preoperative CVR to acetazolamide.

Hemodynamic compromise due to chronic cerebral ischemia in ICA stenosis implies an inadequate collateral blood

flow to maintain the CBF against a further decrease in perfusion pressure. Because ICA clamping during CEA may cause a critical reduction of cerebral perfusion in the area with the hemodynamic compromise, cerebral ischemic events may develop more frequently in patients with hemodynamic compromise than in those without. One study reported that reduction of preoperative cerebrovascular reactivity to acetazolamide measured by brain perfusion SPECT correlates with a high risk of significant cerebral ischemia during ICA clamping (19).

Microembolic signals on intraoperative transcranial Doppler monitoring of the MCA are detected in more than 90% of patients undergoing CEA (4,5). In particular, there is a significant correlation between the number of microembolic signals during dissection of the carotid arteries and development of new postoperative ischemic lesions on DWI (4–9). According to the concept proposed by Caplan and Hennerici (40), preexisting hemodynamic impairment may facilitate the onset of ischemia due to emboli generated from a proximal lesion. One study has demonstrated that reduction of preoperative cerebrovascular reactivity to acetazolamide measured by brain perfusion SPECT predicts the development of new postoperative cerebral ischemic lesions on DWI that are caused by microemboli generated during carotid dissection in CEA (20).

Mechanisms for the development of post-CEA hyperperfusion have been proposed as follows (14): severely reduced cerebral perfusion pressure due to severe ICA stenosis and deficient collateral circulation may lead to maximal dilation of resistance vessels by cerebrovascular autoregulation; after restoration of normal perfusion pressure after CEA, chronically impaired autoregulatory mechanisms may require several days to adjust to the new steady state, resulting in hyperperfusion in the interim. Several investigators have demonstrated that reduction of preoperative cerebrovascular reactivity to acetazolamide measured by brain perfusion SPECT predicts the development of cerebral hyperperfusion after CEA (21–24).

The present study demonstrated that high preoperative CBRBP/CBF AI was a significant independent predictor of both postoperative new cerebral ischemic events and post-CEA hyperperfusion. Because high CBRBP/CBF AI suggests the presence of misery perfusion in the affected hemisphere (33) and resistance vessels maximally dilate due to autoregulatory mechanisms in the misery perfusion, our findings support the theory that preoperative hemodynamic impairment is associated with development of cerebral ischemic events due to intraoperative emboli as well as significant hemispheric hypoperfusion during ICA clamping and that cerebral hyperperfusion results from loss of normal vasoconstriction secondary to chronic cerebral ischemia and maladaptive autoregulatory mechanisms.

The ROC analysis in the present study showed that although the ability to predict development of post-CEA hyperperfusion was similar when comparing CBRBP/CBF AI and preoperative CVR to acetazolamide, the former value

TABLE 2
Risk Factors for Development of Postoperative Cerebral Hyperperfusion on SPECT

Risk factor	Postoperative hyperperfusion		P
	Yes (n = 13)	No (n = 99)	
Age (y)	70.8 ± 6.3	68.4 ± 6.8	0.2726
Male sex	13 (100)	92 (93)	>0.9999
Hypertension	13 (100)	89 (90)	0.6024
Diabetes mellitus	3 (23)	39 (39)	0.3643
Hyperlipidemia	9 (69)	52 (53)	0.3759
Symptomatic lesions	12 (92)	63 (64)	0.0570
Degree of ICA stenosis (%)	89.5 ± 9.8	87.2 ± 8.1	0.0785
Duration of ICA clamping (min)	35.3 ± 4.0	36.3 ± 5.6	0.6198
Preoperative CBRBP/CBF AI	111.2 ± 6.3	101.9 ± 4.8	<0.0001
Preoperative CVR to acetazolamide (%)	6.3 ± 9.9	29.9 ± 10.5	<0.0001

Data are mean ± SD, and data in parentheses are percentages.

predicted development of new postoperative cerebral ischemic events more accurately than did the latter value. The CBRBP/CBF AI also more accurately predicted development of new neurologic deficits immediately after surgery, regardless of whether there were new postoperative cerebral ischemic lesions on DWI. Severe preoperative impairment in cerebral hemodynamics is associated with even worse cerebral hemispheric hypoperfusion during ICA clamping or in the context of cerebral ischemia due to emboli generated from the surgical site (19,20). In the physiologic process known as cerebrovascular autoregulation, misery perfusion is a state of severe hemodynamic impairment (35). Although there is a significant negative correlation between OEF and CVR to acetazolamide, the decrease in CVR and the increase in OEF do not always parallel each other: less than 50% of patients with reduced CVR have an elevated OEF corresponding with misery perfusion (41). In contrast, CBRBP/CBF AI on SPECT provides high sensitivity and high specificity for detection of elevated OEF in the cerebral cortex in patients with chronic unilateral major cerebral artery occlusive disease (33). The difference in the accuracy between CBRBP/CBF AI and CVR for the detection of misery perfusion may also explain the difference between these 2 parameters in their ability to predict new postoperative cerebral ischemic events. Thus, CBRBP/CBF AI may be a useful and alternative SPECT method of predicting the cerebrovascular complications associated with CEA that does not require administration of acetazolamide (with its frequent and various adverse side effects).

The present study possesses several limitations that require discussion. First, the present study included only patients with unilateral ICA stenosis and used affected side-to-contralateral side asymmetry on CBRBP/CBF SPECT images to detect hemodynamic impairment in the affected cerebral hemisphere. However, impairments in cerebral hemodynamics are more severe in patients with bilateral ICA stenocclusive disease than in those with unilateral ICA stenosis (42), and impairments in bilateral cerebral hemodynamics in

patients with bilateral major cerebral arterial occlusive disease may not be detected by the present SPECT method using affected side-to-contralateral side asymmetry. Although absolute quantification of CBRBP using SPECT has been reported (28), this issue of whether CBRBP/CBF values quantified by this method in patients with bilateral ICA stenosis predict development of the cerebrovascular complications associated with CEA remains unclear. Second, normal values were obtained from healthy subjects who were younger than patients with occlusive disease. However, affected-to-contralateral side asymmetry was used to determine CBRBP/CBF value in the affected cerebral hemisphere, which may have minimized the effect of age difference between the 2 populations in the present study.

CONCLUSION

Preoperative CBRBP/CBF images on SPECT more accurately identify patients at risk for cerebrovascular complications occurring during or after CEA when compared with preoperative CVR to acetazolamide.
