Neuroendocrine tumors (NETs) still represent a diagnostic challenge because their clinical presentation is often nonspeciﬁc and usually occurs late in the disease, when metastases are already present ($^i$). Imaging modalities such as CT, MRI, and transabdominal ultrasound are fundamental for diagnosis and staging. However, molecular imaging, including scintigraphy ($^{111}$In-pentetreotide or $^{99m}$Tc-HYNIC-Tyr3-octreotide) and PET staging. However, molecular imaging, including scintigraphy ($^{111}$In-pentetreotide or $^{99m}$Tc-HYNIC-Tyr3-octreotide) and PET with $^{68}$Ga-labeled somatostatin analogs (SSA), is now playing an increasingly important role. In the last 20 years, the molecular imaging of NETs has been changed by the introduction of PET with the $^{68}$Ga-labeled octreotide derivatives ($^{68}$Ga-SSA). Compared with CT and receptor scintigraphy, PET exhibits higher sensitivity, especially in patients with small tumors at the nodal or bone level. Today, the development of PET/CT scanners, whereby molecular and anatomic details are superimposed, has increased diagnostic accuracy, and PET/CT with $^{68}$Ga-SSA ($^{68}$Ga-SSA PET/CT) has become a decision-making technique in the clinical management of NETs. In this regard, the 2007 study by Gabriel et al. was published in The Journal of Nuclear Medicine was the first prospective phase Ib study on a large series of patients comparing the performance of $^{68}$Ga-SSA PET, CT diagnostics, and scintigraphy with SSAs labeled with both $^{99m}$Tc and $^{111}$In (2). The study was performed on patients at 3 different times in the natural history of NETs: diagnosis (patients with clinical or biochemical suspicion of neuroendocrine neoplasia), staging, and follow-up.

The results obtained from the analysis of 84 consecutive patients showed a high sensitivity, speciﬁcity, and accuracy for $^{68}$Ga-SSA PET, with values of 97%, 92%, and 96%, respectively—statistically signiﬁcant with respect to both SPECT and CT.

In particular, the authors showed that $^{68}$Ga-SSA PET was superior to SPECT in 32 patients (38%), especially in the visualization of lesions in the liver and in lymph nodes that were smaller than the $\gamma$-camera—resolving power.

---

$^{68}$Ga-DOTA-Tyr3-Octreotide PET in Neuroendocrine Tumors: Comparison with Somatostatin Receptor Scintigraphy and CT

Michael Gabriel$^1$, Clemens Decristoforo$^1$, Dorothea Kendler$^2$, Georg Dobrohzensky$^3$, Dirk Heute$^3$, Christian Uppimny$^1$, Peter Kovacs$^2$, Elisabeth Van Guggenberg$^2$, Reto Balo$^2$, and Irene J. Virgolini$^1$

$^{1}$Department of Nuclear Medicine, Innsbruck Medical University, Innsbruck, Austria; and $^{2}$Division of Diagnostic Radiology, Innsbruck Medical University, Innsbruck, Austria.

The aim of this study was to evaluate the diagnostic value of a new somatostatin analog, $^{68}$Ga-labeled 1,7,10-triacetatecyclododecane-4,9,9’-N,N’-tetraacetic acid-o-Phe1-Tyr3-octreotide ($^{68}$Ga-DOTA-TOC), for PET in patients with known or suspected neuroendocrine tumors. PET was compared with conventional scintigraphy and dedicated CT. Methods: Eighty-four patients (48 men, 36 women; age range, 28-79 y; mean age = 52 ± 12 y) were prospectively studied. For analysis, patients were divided into 3 groups: detection of unknown primary tumor in the presence of clinical or biochemical suspicion of neuroendocrine malignancy ($n = 13$ patients), initial tumor staging ($n = 36$ patients), and follow-up after therapy ($n = 35$ patients). Each patient received 100-150 MBq $^{68}$Ga-DOTA-TOC. Imaging results of PET were compared with Tc- or 111In-labeled methionine-Tyr3-octreotide ($^{99m}$Tc-HYNIC-TOC) and In$^{111}$-DOTA-TOC. CT was performed on every patient using a multidetector scanner. Each imaging modality was interpreted separately by observers who were unaware of imaging findings before comparison with PET.

The gold standard for defining true-positive (TP), true-negative (TN), false-positive (FP), and false-negative (FN) results was based on available histologic, imaging, and follow-up findings. Results: PET was TP in 69 patients, TN in 12 patients, FP in 1 patient, and FN in 2 patients, indicating a sensitivity of 97%, a specificity of 92%, and an accuracy of 96%. The FP finding was caused by enhanced tracer accumulation in the pancreatic head, and the FN results were obtained in patients with a tumor of the gastrointestinal tract displaying liver metasta-

Neuroendocrine tumors (NET) are a heterogeneous group of neoplasms that originate from the neural crest. These tumors are characterized by their ability to over-express somatostatin (SST) receptors in most cells deriving from so-called neuroendocrine dispersed cells (1). The main primary sites are the gastrointestinal tract and the lung (2,3), but NET can also originate from various other sites, such as the head and neck region or the prostate.

Scintigraphy with radiolabeled SST analogs, first with an $^{111}$In label (4) and subsequently with an $^{187}$Sb label (4,5) and $^{99m}$Tc label (6), has proven useful in diagnosing these tumors. This method also shows the content of SST receptors that might indicate efficacy for treatment with octreotide or other SST analogs (7). Although SST receptor scintigraphy (SRS) shows high efficacy for whole-body imaging, there are some limitations in organs with high physiologic uptake—for example, liver (7,8)—and in terms of detection of smaller lesions due to the detection limits of SPECT for the mentioned radionuclides. $^{18}$F-FDG PET...
The comparison between the accuracy of $^{68}$Ga-SSA PET and CT showed a discrepancy in 34 patients (40.5%); in particular, CT was falsely negative on a skeletal level, with loss of 50% of the lesions. $^{68}$Ga-SSA PET was also able to identify small lesions in unusual locations such as the breast and myocardium. $^{68}$Ga-SSA PET was particularly useful in the visualization of bone metastases, with a higher sensitivity, specificity, and accuracy than a CT scan. In this study of 84 patients (116 PET-positive lesions), only 84 lesions (72.5%) were evident at conventional scintigraphy and only 58 (50%) at CT.

The different diagnostic performances of the 3 investigated methods led to a significant change in patient management and in a different prognostic stratification.

The study, albeit showing some limitations relating mainly to the use of 2 different tracers for scintigraphy, nevertheless demonstrated the fundamental role of molecular imaging with $^{68}$Ga-SSA PET in the management of NET patients. Notably, PET was performed with a PET scanner (GE Healthcare Advance), and the images were sequentially fused with CT. The conclusions, supported by the data presented, were that $^{68}$Ga-SSA PET was superior to SPECT and CT and that the best results were achieved by the combination of PET and CT. The advent of the hybrid PET/CT scanner was a further step forward.

The interest aroused by this work therefore led to an increased number of articles on this topic—articles that have significantly changed the approach to patients with NETs. Furthermore, the development of peptide receptor radionuclide therapy with peptides labeled with β-emitting isotopes such as $^{90}$Y or $^{177}$Lu has paved the way to a more substantial role for nuclear medicine in the management of these tumors, with a significant improvement in the quality of life and outcome of patients (3,4).

Given the scientific evidence produced in the last decade, it was therefore possible to review the guidelines on the management of patients with NETs. Currently, both European and U.S. guidelines (5,6) recommend SSTR PET/CT for diagnosis, staging, and restaging of patients with NETs. Furthermore, the method is mandatory for correct evaluation of the patients who are most likely to benefit from peptide receptor radionuclide therapy.

1Department of Nuclear Medicine, Innsbruck Medical University, Innsbruck, Austria; and 2Division of Diagnostic Radiology I, Department of Diagnostic Radiology, Innsbruck Medical University, Innsbruck, Austria

The aim of this study was to evaluate the diagnostic value of a new somatostatin analog, 68Ga-labeled 1,4,7,10-tetraazacyclododecane-N,N′,N″,N‴-tetraacetic acid-o-Phe1-Tyr3-octreotide (68Ga-DOTA-TOC), for PET in patients with known or suspected neuroendocrine tumors. PET was compared with conventional scintigraphy and dedicated CT.

Methods: Eighty-four patients (48 men, 36 women; age range, 28–79 y; mean age ± SD, 58.2 ± 12.2 y) were prospectively studied. For analysis, patients were divided into 3 groups: detection of unknown primary tumor in the presence of clinical or biochemical suspicion of neuroendocrine malignancy (n = 13 patients), initial tumor staging (n = 36 patients), and follow-up after therapy (n = 35 patients). Each patient received 100–150 MBq 68Ga-DOTA-TOC. Imaging results of PET were compared with 99mTc-labeled hydrazinonicotinyl-Tyr3-octreotide (99mTc-HYNIC-TOC) and 111In-DOTA-TOC. CT was also performed on every patient using a multidetector scanner. Each imaging modality was interpreted separately by observers who were unaware of imaging findings before comparison with PET. The gold standard for defining true-positive (TP), true-negative (TN), false-positive (FP), and false-negative (FN) results was based on all available histologic, imaging, and follow-up findings.

Results: PET was TP in 69 patients, TN in 12 patients, FP in 1 patient, and FN in 2 patients, indicating a sensitivity of 97%, a specificity of 92%, and an accuracy of 96%. The FP finding was caused by enhanced tracer accumulation in the pancreatic head, and the FN results were obtained in patients with a tumor of the gastrointestinal tract displaying liver metastases. 68Ga-DOTA-TOC showed higher diagnostic efficacy compared with SPECT (TP in 37 patients, TN in 12 patients, FP in 1 patient, and FN in 34 patients) and diagnostic CT (TP in 41 patients, TN in 12 patients, FP in 5 patients, and FN in 26 patients). This difference was of statistical significance (P < 0.001). However, the combined use of PET and CT showed the highest overall accuracy. Conclusion: 68Ga-DOTA-TOC PET shows a significantly higher detection rate compared with conventional somatostatin receptor scintigraphy and diagnostic CT with clinical impact in a considerable number of patients.

Key Words: 68Ga; PET; DOTA-Tyr3-octreotide; neuroendocrine tumors; somatostatin receptor scintigraphy; diagnostic CT

Neuroendocrine tumors (NET) are a heterogeneous group of neoplasms that originate from the neural crest. These tumors are characterized by their ability to over-express somatostatin (SST) receptors in most cells deriving from so-called neuroendocrine dispersed cells (1). The main primary sites are the gastrointestinal tract and the lung (2,3), but NET can also originate from various other sites, such as the head and neck region or the prostate.

Scintigraphy with radiolabeled SST analogs, first with an 123I label (4) and subsequently with an 111In (4,5) and 99mTc label (6), has proven useful in diagnosing these tumors. This method also shows the content of SST receptors that might indicate efficacy for treatment with octreotide or other SST analogs (7). Although SST receptor scintigraphy (SRS) shows high efficacy for whole-body imaging, there are some limitations in organs with higher physiologic uptake—for example, liver (7,8)—and in terms of detection of smaller lesions due to the detection limits of SPECT for the mentioned radiotracers. 18F-FDG PET scanning is another widely accepted imaging approach in clinical oncology. Although 18F-FDG PET shows high spatial resolution, unlike for many other malignancies, it is not indicated primarily for NET because of its poor sensitivity to detect tumors with low metabolic activity and slow growth (9).

On the other hand, morphologically oriented imaging techniques, such as contrast-enhanced multidetector CT, permit rapid volumetric acquisition and dynamic analysis of the contrast agent, which provides higher image resolution and gives information about the vascular enhancement pattern (10). However, these methods sometimes lack specificity, as conclusions regarding malignant involvement of organ structures are based only on size criteria and the contrast enhancement pattern (11).

Initial patient studies have demonstrated the capability of PET technology using 68Ga-labeled 1,4,7,10-tetraazacyclododecane-N,N′,N″,N‴-tetraacetic acid-o-Phe1-Tyr3-octreotide (68Ga-DOTA-TOC) (12,13). This method clearly offers higher resolution and improved pharmacokinetics compared with SRS, with promising results in the detection of SST receptor-expressing tumors.

The aim of the present study was to provide data on diagnostic efficacy of the new radiopharmaceutical 68Ga-DOTA-TOC for PET in a larger series of patients with known or suspected NET. The study included comparison with SPECT and CT. Patient and site-related differences of the 3 imaging modalities were analyzed in a head-to-head comparison by means of image fusion.

MATERIALS AND METHODS

Patients

From September 2004 to April 2006, 84 consecutive patients (48 men, 36 women; age range, 28–79 y; mean age ± SD, 58.2 ± 12.2 y)
were enrolled in this prospective phase IIb study. For analysis, the patients who were investigated were divided into 3 groups (14): The first group consisted of patients who underwent imaging for the initial detection and localization of suspected NET and potential metastases in the presence of clinical or biochemical suspicion (detection; n = 13). Patients with histologically proven neuroendocrine malignancies were enrolled for staging purposes in the second group (staging; n = 36). In the third group, patients were referred during posttherapy follow-up (follow-up; n = 35) to exclude or to detect tumor recurrence. In the last 2 groups, at least 1 tumor manifestation was histologically confirmed in patients with multiple metastases. The patient characteristics are summarized in Table 1.

Four patients had hypoglycemia with symptoms of both neuroglycopenia and catecholamine response. During symptoms, blood glucose levels were <40 mg/dL. Therefore, a pancreatic islet cell tumor was considered in these patients.

NET are generally differentiated between those producing hormone-related symptoms (e.g., flush or diarrhea) and those presenting without any hormonal symptoms. Accordingly, 27 patients with clinical and biochemical signs for a secreting tumor and 57 patients with a non-functional tumor were included.

In patients who were referred for restaging during follow-up (n = 35), various therapeutic procedures were performed before inclusion. Most of these patients were treated by surgery (n = 29), some of them without further treatment (n = 6). Additional drug therapy was administered to 23 patients. Seven patients were treated with chemotherapy, and 16 patients were treated with long-acting SST analogs alone or in combination with interferon-α.

Written informed consent was obtained from all patients before being included in the study, and the study was approved by the local ethics committee.

**PET**

Preparation of $^{68}$Ga-DOTA-TOC. $^{68}$Ga-DOTA-TOC was prepared using a modification of the method described by Breeman et al. (15). Briefly, a TiO$_2$-based commercially available $^{68}$Ge/$^{68}$Ga generator (Cyclotron Inc.) was eluted with 0.1N hydrochloric acid, and a 1.2-mL fraction was added to 20-40 μg of DOTA-TOC; pH was adjusted to 3.5-4.0 by adding 1 mol/L sodium acetate solution, which was followed by heating to 100°C for 7 min. The reaction solution was passed over a C$_18$ cartridge (Sep-Pak; Waters), washed with 4 mL of water, and finally eluted with 0.5 mL 95% ethanol, which was followed by saline through a 0.2-μm sterile filter. Radiochemical purity, as determined by instant thin-layer chromatography and high-performance liquid chromatography, exceeded 95% in all cases.

Data Acquisition and Processing. Data acquisition was performed by means of a dedicated PET scanner (GE Advance) with 15-cm axial field of view (FOV) and 55-cm transaxial FOV. Patients were imaged in 2-dimensional mode using septa. The duration of acquisition was 5 min per bed position (axial FOV) in emission mode. For the evaluation of the best imaging time, 3 emission image sets were acquired at 20, 60, and 100 min after injection. Because of scan time limitations, the first and last acquisitions scanned only the torso (4 bed positions), whereas the acquisition at 1 h after injection was performed as a whole-body scan (from head to middle of the upper leg, usually 7 bed positions). Attenuation correction was performed by means of transmission data ($^{68}$Ga pin source, 3 min per bed position). Image reconstruction was performed with the system’s implementation of the ordered-subsets expectation maximization iterative algorithm, using segmented attenuation correction and model-based scatter correction. The settings for iterative reconstruction were 2 iterations and 26 subsets, with 4-mm full width at half maximum (FWHM) interpulse filtering and 6-mm FWHM after filtering. The attenuation correction settings were set to segmented correction with 10-mm smoothing. No axial smoothing was performed for either emission or transmission data. For the first 8 patients, average tissue standardized uptake values (SUVs) (SUV$_{max}$, units of g/mL; bw indicates body weight) have been determined by means of manually drawn regions of interest delineating the respective tissue thresholded to 50% of the maximum uptake in that tissue.

**SRS**

$^{99m}$Tc-Labeled hydrazinonicotinyl-Tyr$_3$-octreotide ($^{99m}$Tc-HYNIC-TOC) was prepared using a kit formulation as recently described (16). Each patient received a mean activity of 400 MBq (intravenously) of the tracer. Whole-body imaging was performed at 2 and 4 h after injection using a dual-detector VertexPlus scintillation camera (Philips), which was followed by SPECT (6). The scan speed for whole-body imaging was 10 cm/min when using the $^{99m}$Tc-labeled derivative. The camera was equipped with a low-energy, all-purpose, parallel-hole collimator (window setting, 140 keV; width, 10%; 180° rotation detector head; 64 projections; 128 x 128 matrix; 40-s acquisition time per projection). The SPECT image data were reconstructed by standard filtered backprojection using a Butterworth filter.

DOTA-TOC was radiolabeled as reported elsewhere (17). $^{111}$In-DOTA-TOC whole-body scintigraphy in anterior and posterior views was performed at 4, 24, and 48 h after a single-dose injection of 150 MBq of the $^{111}$In-labeled radiopharmaceutical. Scintigraphic acquisitions were obtained with the same doublehead γ-camera as described (ADAC; VertexPlus), equipped with a medium-energy, parallel-hole collimator (window setting, 172 and 246 keV; window width, 20%). The scan speed for whole-body imaging was 5 cm/min using the $^{111}$In-labeled radiopharmaceutical.

SPECT was acquired after 24-h whole-body imaging using the same reconstruction algorithm as mentioned earlier.

Sixty-six patients were investigated with only 1 tracer: 33 patients with $^{99m}$Tc-HYNIC-TOC and 33 with $^{111}$In-DOTA-TOC. In 18 patients, both radiopharmaceuticals were used for comparison with PET and CT.

**CT and Image Fusion Procedure**

Helical CT scans of the thorax and the abdomen with a slice thickness of 2.5 mm were obtained with the HiSpeed CTi Advantage scanner (GE Healthcare). Typically, 150 mL (twice the weight of the patient in kilograms) iopromidum contrast media (Ultravist 370; Schering) were administered at 5 mL/s, with scan delays of approximately 30 s for the late arterial phase and 70 s for the portal phase.

For image fusion, the PET, SPECT, and CT scans were performed sequentially using an individualized vacuum mattress with external markers attached to it. For every image acquisition (PET, SPECT, and CT), the patient was repositioned into the vacuum mattress (11). The image fusion procedure was used for anatomic delineation of abnormal findings in SPECT and PET.

**Interpretation and Data Evaluation**

PET and SPECT studies were interpreted independently by 2 experienced nuclear medicine physicians. Corresponding studies were compared lesion by lesion for final analysis and ruled as matching or mismatching by the 2 nuclear medicine specialists. If the result of the 2 viewers was discordant, a third reader—who acted as referee—was consulted. They were aware of the patients’ clinical history, which was provided by the referring physician but were unaware of any result of other imaging modalities. The criteria for image interpretation of PET and SPECT are summarized.

</table>
Table 2. As a measure for diagnostic yield, the number of lesions that could be identified clearly as single foci was determined. Lesions within the liver were rated as 1 organ metastasis, considering the irregular configuration and confluence of some lesions, so that an individual metastasis frequently was not delineated. A lesion-by-lesion analysis was performed for all other tumor foci. Concordant findings on nuclear medicine techniques (PET and SPECT) and CT meant that both techniques (PET or SPECT and CT) were consistent with malignancy. In the case of discrepancies with regard to nuclear medicine and CT findings, further assessment of abnormal foci was conducted.

mandatory—that is, by histologic proof or follow-up controls with CT or MRI after 3 mo and, if necessary, after 6 mo. If malignant evolution on follow-up or progression on therapy was observed, these suggestive findings were considered malignant for the final decision. Those patients with no abnormal findings were monitored over a period of at least 6 mo with repeated CT or MR scans before a scan result was considered true-negative (TN).

CT and, if necessary, MR scans were interpreted by experienced radiologists who were unaware of the scintigraphic results. A positive diagnosis was based on the specific appearance of malignant disease derived from NET as reported elsewhere (18).

Thus far, abnormal findings were assessed histologically in 13 patients. Repeated clinical examinations with CT were performed in 73 cases and with MR in 22 cases. More details are given in Table 1. Attention has been directed toward unproven findings of the scans.

**Statistical Analysis**

The results of the 3 imaging modalities (PET, SPECT, and CT) were classified as true-positive (TP), TN, false-positive (FP), or false-negative (FN) according to the reference standard, as described earlier. The \( \chi^2 \) test for independence, or the Fisher exact test when appropriate, was used to evaluate differences in lesion detectability when subgroups of the patients being investigated were statistically compared (\(^{111}\)In-DOTA-TOC vs. \(^{99m}\)Tc-HYNIC-TOC and secreting vs. nonsecreting tumors). The McNemar test of correlated properties was used to statistically compare the imaging results of \(^{68}\)Ga-DOTA-TOC PET with SPECT and diagnostic CT. Analysis was done on a lesion basis and on a patient basis. All \( P \) values < 0.05 were considered significant. Cohen’s \( \kappa \)-statistic with 95% confidence intervals was calculated to show the degree of association between the techniques. The function of uptake over time was assessed using linear regression analysis.

For evaluation of the clinical value of \(^{68}\)Ga-DOTA-TOC PET in comparison with the other imaging modalities, organ systems were assessed for recognition of any lesion in the tissue. The focus of interest was related to unknown tumor lesions arising in organ systems, unaware of malignant involvement from other imaging modalities.

| Malignant | Clearly demarked findings with higher tracer uptake compared with liver uptake  
| | Tracer accumulation in structures that did not take up tracer physiologically or was higher than background activity  
| | Pancreatic head: irregular or protrusive shape of finding; clear delineation from adjacent tissue with higher uptake than liver uptake |

**FIGURE 1.** A 28-y-old female was referred for primary diagnosis of a NET because of elevated tumor markers in serum. PET (A) clearly depicted an abnormal focus in upper abdomen (arrow). This lesion could be delineated in the pancreas after image fusion with CT (B). There was also increased contrast medium enhancement in the margin when using helical CT (C). SPECT with \(^{99m}\)Tc-HYNIC-TOC was also positive for this tumor in upper abdomen (D). This positive finding was confirmed by histopathology revealing a NET with 1 cm in diameter. RESULTS

Biodistribution of \(^{68}\text{Ga-DOTA-TOC}\)

Uptake of \(^{68}\text{Ga-DOTA-TOC}\) was routinely found in neuroendocrine tissue (pituitary and adrenal glands) and in 57 patients (67.8%) in the pancreatic head without known pathology. Additionally, the spleen and the urinary excretion system also showed enhanced tracer accumulation. Homogeneous uptake was observed in the liver and in 34 patients (40.4%) in the thyroid gland. Because of the excellent tumor-to-organ contrast, NET lesions could be easily identified by visual analysis (Fig. 1). However, anatomic delineation of abnormal findings was difficult without image fusion because of highly specific tracer uptake. Intravenous injection of \(^{68}\text{Ga-DOTA-TOC}\) was well tolerated in all patients, and no side effects were observed in any patients after tracer injection. On the basis of an initial evaluation of 8 patients, the optimal time of acquisition was determined to be 100 min after injection. In 1 of these 8 patients, 2 additional thoracic findings were observed when comparing late acquisition 100 min after injection with the earlier acquisition (patient 12). The acquisition protocol was adapted after this initial series with only 1 single whole-body scanning at 100 min after injection. Linear regression analysis of tumor uptake values shows a significant increase in SUVs of 14% (60 min vs. 20 min, \(R^2 = 0.96\)), 9% (100 vs. 60 min, \(R^2 = 0.97\)), and 24% (100 vs. 20 min, \(R^2 = 0.89\)) Interpatient SUVs at different times are given in Table 3.

Analysis on Patient Basis

Results from all 84 patients studied are summarized in Table 4. Among the 84 patients, \(^{68}\text{Ga-DOTA-TOC}\) PET was TP in 69 (82.1%), TN in 12 (14.3%), FP in 1 (1.2%), and FN in 2 (2.4%) patients, indicating a sensitivity of 97% (69/71 patients), a specificity of 92% (12/13 patients), and an accuracy of 96% (81/84 patients) on a patient basis. An analysis per patient comparing the scan results of PET with SPECT and with diagnostic CT emphasizes the improved diagnostic efficacy of \(^{68}\text{Ga-DOTA-TOC}\), with a \(P\) value of \(<0.001\) using the McNemar test (Table 5). Cohen’s \(\kappa\)-statistic of 0.3 showed only fair association between the techniques.

Analysis on Lesion Basis

\(^{68}\text{Ga-DOTA-TOC}\) PET studies detected 375 abnormal findings in 70 patients, of which 374 were TP and 1 was FP. This FP finding was found in patient 30, who had clinical symptoms suggestive of a secreting NET and elevated tumor markers (chromogranin A [CgA] of 34.6 U/L and neuron-specific enolase [NSE] of 26.7 \(\mu\)g/L) and who presented with enhanced tracer uptake in the pancreatic head. Surgical exploration was negative, and histology and further follow-up controls did not confirm this finding to be malignant. Overall, 23 abnormal findings in 22 patients were considered malignant in the pancreas. Fourteen of those were found in the pancreatic head, with 1 FP finding.

\(^{68}\text{Ga-DOTA-TOC}\) was FN in 2 patients. A 47-y-old woman was referred for initial staging of a NET unknown primary (patient 36). PET and SPECT were negative for multiple liver metastases that were histologically confirmed by biopsy. Both nuclear medicine techniques were also negative for histologically confirmed small liver metastases in the other patient, a 67-y-old man (patient 78). This patient was referred for follow-up after surgery and chemotherapy of a rectal tumor. In both patients, diagnostic CT revealed a TP scan result.

\(^{68}\text{Ga-DOTA-TOC}\) and Functional Status of NET

The fraction of patients with clinical and biochemical features of a NET consisted of 18 TP, 8 TN, and 1 FP results, whereas in the group of patients with nonfunctioning tumors, 51 TP, 4 TN, and 2 FN results were observed. When comparing both groups, no statistically significant difference was found for PET (\(P = 0.96\)). Both patients with the FN scan result did not show any functional activity of the tumor, whereas the FP result was observed in a patient with elevated CgA level and persisting diarrhea, suggestive of a hormone-active tumor, as mentioned earlier.

PET Versus Scintigraphy (SPECT) and Diagnostic CT

All 3 modalities (PET, SPECT, and CT) showed an equivalent scan result in 39 patients (46.4%), including 27 TP and 12 TN results (Fig. 1).

Discrepancies between PET and SPECT were found in 32 patients (38%), all of whom were TP with PET and FN with SPECT. In this patient group, liver metastases were missed in 10 cases. Twenty-two additional small lymph node metastases also were not detected with

Number of patients is in parentheses.
SPECT in 15 patients. In 2 patients with carcinoid tumors, small peritoneal deposits escaped detection with SPECT. Furthermore, 32 bone metastases were not delineated by conventional scintigraphy but were positive with $^{68}$Ga-DOTA-TOC PET. Discrepancies between PET and CT were found in 34 patients (40.5%), of whom there were 2 TP, 1 TN, 5 FP, and 26 FN findings with CT. FP findings with CT were caused by suggestive small nodular lung lesions in 2 patients and in 2 additional cases by enlarged lymph nodes. One 55-y old male patient was referred for initial detection of a NET in the case of elevated CgA levels (patient 52). Abdominal CT visualized a lesion in the wall of the jejunum with a diameter of 1.4 cm. The contrast medium showed enhanced uptake of a primary NET. However, PET and SPECT were negative. Surgical exploration revealed a benign leiomyoma, which was proven by histology. Site-related differences are illustrated in Table 6.

Eighteen patients were investigated with both SPECT tracers, yielding a comparable scan result. The $^{99m}$Tc-labeled compound was TP in 18 patients, TN in 11, FP in 1, and FN in 21 patients. When using $^{111}$In-DOTA-TOC, the scan result was TP in 29 patients, TN in 1, and FN in 21 patients. No statistically significant difference was observed between the 2 groups ($P = 0.84$).

**Clinically Valuable Information Obtained by PET**

In 18 patients (21.4%), $^{68}$Ga-DOTA-TOC provided further clinically relevant information in comparison with diagnostic CT alone, including 9 patients with unknown bone metastases (Fig. 2). The primary tumor or residual tumor at the primary site was demonstrated in 5 patients with $^{68}$Ga-DOTA-TOC PET but escaped detection by CT.

A 61-y-old woman (patient 65) was referred after treatment of a pulmonary carcinoid tumor for follow-up. Diagnostic CT was negative, but PET revealed small metastatic lesions in the myocardium and in the pancreas, with focally enhanced tracer accumulation. Multiple liver metastases were known in a 47-y-old woman (patient 80) who was investigated during follow-up after surgical resection of a small bowel carcinoid. $^{68}$Ga-DOTA-TOC additionally showed a small lesion in the right breast initially not found with the other 2 modalities (Figure 3). This lesion with a diameter of 7–4 mm and 3 other metastases in the liver were surgically removed. In 2 patients, small liver metastases were not shown with diagnostic CT and SPECT (Fig. 4).

Compared with scintigraphy, $^{68}$Ga-DOTA-TOC PET provided further valuable clinical information in 12 patients (14.3%). Three patients have just been mentioned. Unknown bone metastases were shown in 5 patients. Surgical intervention was omitted in 3

Other sites include, but are not mentioned, locations of tumor deposits—for example, peritoneal carcinosis.

**TABLE 6**

**Site-Related Findings**

**FIGURE 2.** A 56-y-old woman with multiple liver and lymph node metastases was referred for restaging after surgery and chemotherapy. CT presented these tumor lesions; however, it was negative for bone lesions. Beside the visceral metastases, some additional osteoblastic and osteolytic bone metastases were clearly depicted with $^{68}$Ga-DOTA-TOC (A). Only some of these bone metastases were delineated by conventional scintigraphy (B, anterior view; C, posterior view). Osteoblastic bone lesions were confirmed by $^{18}$F-Na-fluoride PET (D). Retrospective CT analysis after image fusion revealed some of these bone metastases.
patients because widespread disease was detected by $^{68}$Ga-DOTA-TOC, showing additional unknown distant tumor lesions. One 34-‐y-‐old male patient was investigated after chemotherapy and chemoembolization of metastatic lesions in the liver of a NET unknown origin. PET additionally showed the primary tumor in the pancreatic head and local lymph node metastases (patient 34).

**DISCUSSION**

SRS has gained widespread acceptance as the imaging method of choice in NET patients, showing high sensitivity and good specificity for detection of the primary tumor and secondary lesions (4,14,19–21). However, because of low spatial resolution, this technique has a poor capability to detect lesions with smaller size and lower receptor density. $^{68}$Ga-DOTA-TOC has emerged as a new PET tracer showing better results compared with conventional nuclear medicine examinations in a small group of patients (12,13). Initial results were confirmed by our prospective study in a larger number of patients with statistically significant higher diagnostic accuracy compared with conventional SRS as well as diagnostic CT. In 25% (21/84) of patients with NET, $^{68}$Ga-DOTA-TOC provided additional information that was obtained with none of the other imaging procedures.

The better imaging properties are based on the higher spatial resolution of PET and on some beneficial pharmacokinetic properties of $^{68}$Ga-DOTA-TOC (22) but also need an optimal acquisition protocol. Therefore, in 8 patients images were acquired at different times to evaluate the optimal time for acquisition, which turned out to be 100 min after injection by calculation of SUVs. SUVs were not used for diagnostic purposes, especially as the threshold and averaging method applied in this article is too complex for routine clinical use. Nevertheless, we do not rule out that simple maximum SUVs might be feasible as a clinical tool, taking into account our results.

The difference in detection rate was most pronounced for bone metastases—that is, of all 116 PET-positive lesions, SPECT delineated 84 (72.5%) lesions and CT delineated only 58 lesions (50%). These additional findings have prompted therapeutic interventions in some patients but also have a prognostic implication because unknown distant bone metastases are considered as a negative prognostic factor, possibly requiring a more aggressive treatment regime (23,24). On the other hand, some limitations can be found in the detection of liver metastases using $^{68}$Ga-DOTA-TOC, as it is also known for SPECT (7,8). Radiologic techniques are found to be valuable for evaluation of this organ, in which metastases are frequently found in NET patients (25,26). In the present study the combined use of PET and CT also showed the highest overall accuracy for diagnosis of liver metastases, as CT provided complementary information in those 2 patients who were negative with PET. Diagnostic CT additionally reveals the individual anatomy,
assisting in delineation of abnormal findings, which was very important in many patients when using $^{68}$Ga-DOTA-TOC. On the other hand, tumor deposits—for example, bone metastases—frequently escaped detection by initial CT evaluation. Some of these lesions, however, were consecutively identified after image fusion in the CT scan guided by the findings of the PET scan. This implies that the PET scan is an excellent method for screening of tumor lesions followed by a more directed CT.

The very specific binding of $^{68}$Ga-DOTA-TOC may lead to overinterpretation of tracer accumulation. Therefore, interpretation should be done cautiously in organs showing physiologically enhanced tracer uptake. The only FP case, for instance, was found in a patient with clinical features suggestive of a NET presenting focally enhanced tracer uptake in the pancreatic head mimicking the tumor.

One limitation of this study is based on the use of 2 different compounds for conventional scintigraphy, $^{99m}$Tc-HYNIC-TOC and $^{111}$In-DOTA-TOC. However, it has been shown for both radiopharmaceuticals that the detection capability for NET is comparable with $^{111}$In-DTPA-$\beta$-Phe$^1$-octreotide (where DTPA is diethylenetriaminepentaacetic acid) (6,17,27). Equivalent scan results were also obtained with both tracers in some patients, and no statistical difference was observed when $^{99m}$Tc-HYNIC-TOC was compared with $^{111}$In-DOTA-TOC. Therefore, conventional scintigraphy, including SPECT acquisition, was confined to 1 group for head-to-head comparison with PET.

$^{11}$C-5-Hydroxytryptophan and $^{18}$F-fluoro-L-3,4-dihydroxyphenylalanine are substrates of the intermediary metabolic pathway in terms of the APUD concept (where APUD is amine precursor uptake and decarboxylation). Promising results have been obtained with both radiopharmaceuticals in patients with NET, exceeding the detection rate of SPECT and CT (28,29). A limitation of this concept seems to be that nonfunctioning tumors may be difficult to detect, as accumulation reflects the secretion pattern of peptide hormones (28). Furthermore, a decision on

FIGURE 4. A 62-y-old male patient was investigated after resection of a small bowel carcinoid. $^{68}$Ga-DOTA-TOC PET displayed multiple small liver metastases (A). These liver lesions were negative with the other 2 modalities, CT and scintigraphy (B) including SPECT (C). Ultrasonography (D) and further follow-up controls confirmed these lesions. Diameters of metastases were in the range of 1 cm. Positive PET finding initiated treatment with $^{177}$Lu-DOTA$^{\beta}$Tyr$^3$,Thr$^8$]octreotide ($^{177}$Lu-DOTA-TATE).
treatment using $^{90}$Y-DOTA-TOC or $^{177}$Lu-DOTA[Tyr3,Thr8] octreotate ($^{177}$Lu-DOTA-TATE) cannot be made on the basis of the uptake behavior in tumor lesions. In contrast, several patients were successfully treated with radiotope therapy because of a positive pretherapeutic scan result with $^{68}$Ga-DOTA-TOC. With regard to patient convenience, it should be stressed that the whole investigation can be performed within 2 h, thereby creating lower radiation burden compared with some other nuclear medicine techniques as indicated by preclinical (30) and clinical studies (12,13).

The use of a generator for a short-lived radionuclide such as $^{68}$Ga provides the basis for convenient, easy use of this radionuclide. Labeling of DOTA-derivatized peptides is straightforward and can be performed in a very short time (<30 min). This guarantees a high flexibility and good availability of this radiopharmaceutical in clinical routine in contrast to $^{111}$In-labeled compounds, requiring access to an on-site cyclotron unit, or some $^{18}$F-labeled derivatives, such as N-((1-deoxy-α-fructosyl)-N-(2-fluoroproionyl)-Lys2,Tyr3-octreotate (Gluc-Lys$^{18}$F-FP)-TOCA) (37), requiring multistep synthesis with several purification steps.

**CONCLUSION**

Somatostatin receptor PET with $^{68}$Ga-DOTA-TOC is superior for the detection of NET compared with SPECT and diagnostic CT in various clinical situations (initial diagnosis, staging, and follow-up). The higher sensitivity for tumor detection has clinical impact in a considerable number of patients, especially when compared with CT. However, the best results are to be achieved by the combination of PET and CT. It also indicates receptor expression for targeted radiotope therapy.
