Caffeine consumption before adenosine stress myocardial perfusion imaging (MPI) is known to affect the hemodynamic response and, thus, reduce the stress myocardial blood flow (MBF) and myocardial flow reserve (MFR) assessments. However, it is not clear if any sex-specific differences in the hemodynamic response after caffeine consumption exist. This study aimed to evaluate if such differences exist and, if so, their impact on MBF and MFR assessments. **Methods:** This study comprised 40 healthy volunteers (19 women). All volunteers underwent 4 serial rest/stress MPI sessions using $^{82}$Rb; 2 sessions were acquired without controlled caffeine consumption, and 2 sessions after oral ingestion of either 100 and 300 mg of caffeine or 200 and 400 mg of caffeine. For the caffeine imaging sessions, caffeine was ingested orally 1h before the MPI scan. **Results:** Increase in plasma caffeine concentration (PCC) (mg/L) after consumption of caffeine was larger in women (MPI session without caffeine vs. MPI session with caffeine: women $0.3 ± 0.2$ vs. $5.4 ± 5.1$, men $0.1 ± 0.2$ vs. $2.7 ± 2.6$, both $P<0.001$). Caffeine consumption led to reduced stress MBF and MFR assessments for men whereas no changes were reported for women (women [PCC < 1 mg/L vs. PCC ≥ 1 mg/L]: stress MBF = $3.3 ± 0.6$ vs. $3.0 ± 0.8$ mL/g/min, $P=0.07$; MFR = $3.7 ± 0.6$ vs. $3.5 ± 1.0$, $P=0.35$; men [PCC < 1 mg/L vs. PCC ≥ 1 mg/L]: stress MBF = $2.7 ± 0.7$ vs. $2.1 ± 1.0$ mL/g/min, $P=0.005$; MFR = $3.8 ± 1.0$ vs. $3.1 ± 1.4$, $P=0.018$). Significant differences in the stress MBF were observed for the 2 sexes (both $P<0.001$), whereas similar MFR was reported (both $P ≥ 0.12$). **Conclusion:** Associations between increases in PCC and reductions in stress MBF and MFR were observed for men, whereas women did not have the same hemodynamic response. Stress MBF was affected at lower PCCs in men than women.

**Key Words:** caffeine; adenosine; myocardial flow reserve; PET; stress myocardial blood flow

DOI: 10.2967/jnumed.121.261970

---

Myocardial blood flow (MBF) and myocardial flow reserve (MFR) assessments have become central in the clinical assessment of cardiac $^{82}$Rb in PET. The valid measures of stress MBF and MFR require a full hemodynamic response during the acquisition. Adenosine is a frequently used pharmacologic stressor that attaches to the A$_{2A}$-adenosine receptor that mediates coronary vasodilation (1,2). When using adenosine as a pharmacologic stressor, patients are recommended to refrain from beverages, food, and analgesics containing caffeine for at least 12 h before the imaging session to avoid subpar stressing of the patients as caffeine nonselectively blocks the A$_{2A}$-adenosine receptor (1–3). Consumption of caffeine has been shown to reduce the hemodynamic response even at plasma concentrations as low as 1 mg/L, which might introduce false-positive findings after the consequent reductions in the stress MBF and MFR (4–6). Although elevated caffeine plasma concentrations are known to affect the hemodynamic response when using adenosine as a stressing agent (4,5,7), it is unknown whether any sex-specific differences in the hemodynamic response exist (5,8).

This study aimed to evaluate the potential influence of sex on the association between plasma caffeine concentrations and stress MBF and MFR, respectively.

**MATERIALS AND METHODS**

**Study Population**

This study comprised 40 young healthy volunteers (19 women) (median age = 23 y, interquartile range [IQR] = 22; 25) recruited for rest/adenosine-stress myocardial perfusion $^{82}$Rb PET/CT from September 2016 to March 2017. Median volunteer weight was 70.0 kg (IQR = 62.0; 79.5 kg), with corresponding median body mass index of 22.0 (IQR = 20.5; 23.8). The volunteers underwent 4 serial PET/CT imaging sessions within 27 d (IQR = 17; 36), acquired with and without controlled caffeine consumption before the imaging session. Inclusion criteria were age >18 y, no participation in studies testing drugs, no regular consumption of medicine, no known medical condition, and no use of tobacco and euphoric substances (except alcohol) within 3 mo before study participation. Exclusion criteria were pregnancy, allergy, intolerance to theophylline or adenosine, any prior medical history of asthma, or inability to adhere to the study protocol. The Scientific Ethics Committee of the Capital Region of Denmark (protocol no. H-15009293) and the Danish Data Protection Agency approved this study, and all volunteers provided informed oral and written consent.

**Imaging Protocol**

**PET Acquisition.** The 40 healthy volunteers were divided into 2 groups, both undergoing 4 $^{82}$Rb PET/CT imaging sessions, each...
consisting of an $^{82}$Rb rest–stress protocol (Fig. 1A). All PET acquisitions, targeting injection doses of $1,100$ MBq (30 mCi) $^{82}$Rb, were obtained in 3-dimensional mode on a 128-slice Biograph mCT PET/CT system (Siemens Healthineers) and stored in list-mode format (9). Pharmacologic stressing was obtained using adenosine infused at 140 µg/kg/min for 6 min with PET emission acquisition starting 2.5 min into the infusion (Fig. 1A). Before the rest scans, the volunteers underwent a low-dose CT for attenuation-correction purposes (120kVp; effective tube current, 26 mA [11 mAs quality reference]) acquired using a free-breathing protocol (10). The volunteers were instructed to abstain from caffeine at least 24 h before each of the 4 imaging sessions. All study volunteers underwent 2 imaging sessions without ingestion of caffeine and 2 imaging sessions after the ingestion of caffeine in a controlled setting using caffeine tablets (Fig. 1B). The caffeine tablets were dissolved in hot water and orally ingested 60 min before the rest perfusion scans. One-half of the volunteers had 2 serial imaging sessions with ingestion of 100 and 300 mg of caffeine, whereas the other half of the study volunteers underwent 2 serial imaging sessions after the ingestion of 200 and 400 mg of caffeine (Fig. 1B). The 4 imaging sessions were obtained in a randomized fashion. For this study, the plasma caffeine concentration is reported at the time of the stress myocardial perfusion imaging (MPI), thus, as an average of the measurements obtained at 75 and 90 min. All plasma caffeine concentrations were measured using high-performance liquid chromatography-mass spectrometry.

PET Reconstruction Protocol and Data Processing. The 6-min-long PET acquisitions were reconstructed into dynamic image series consisting of 18 frames (1 $\times$ 10, 8 $\times$ 5, 3 $\times$ 10, 2 $\times$ 20, and 4 $\times$ 60 s) using the vendor iterative ordered-subset expectation-maximization 3-dimensional reconstruction method (2 iterations, 21 subsets), with corrections for time of flight and point-spread function. All data were smoothed using 6.5-mm gaussian postfiltering. MBF was calculated using the Lortie model (11), and MFR was calculated as the ratio of the stress and rest MBF (12) in dedicated software (QPET; Cedars-Sinai Medical Center (13)). We report MBF and MFR with and without corrections for the rate–pressure product (RPP), defined as RPP = (systolic blood pressure/(heart rate)); corrected rest MBF = (rest MBF)/RPP $\times$ 6,500 and corrected stress MBF = (stress MBF)/RPP $\times$ 8,600. Stress MBF and MFR above 3.0 were considered normal (14).

Repeatability. Test–retest repeatability of the rest and stress MBF and the MFR were calculated for the baseline scans (0 mg of caffeine ingested) with plasma caffeine concentrations $< 1$ μg/mL using the coefficient of variance (15).

Coronary Vascular Resistance (CVR). CVR was obtained for all scans using Equation 2 (16).

\[
CVR = 0.33 \times \frac{(2 \times \text{diastolic blood pressure} + \text{systolic blood pressure})}{\text{MBF}}
\]  

(Eq. 1)

In Equation 2, MBF represents the scan-specific MBF. Both diastolic and systolic blood pressures were obtained during the PET emission acquisitions.

Regression plots for correlation between ingested caffeine and blood plasma concentration caffeine were calculated for all scans, using averaged plasma caffeine concentrations obtained at 75 and 90 min.

Concentration–response curves were obtained using a nonlinear curve-fit model, and the half-maximal relaxation (EC50, half-maximal effective concentration) was determined:

\[
y = \text{bottom} + \frac{(\text{top} - \text{bottom})}{1 + (\text{logEC50} - x) + \text{slope}}
\]  

(Eq. 2)

Statistical Analysis

Differences in the MBF and MFR were quantified using multivariable analyses (ANOVA) in R (GNU project). Descriptive analyses of continuous values were reported as mean ± SD and range or median and IQR. Two-tailed $P$ values of less than 0.05 were considered statistically significant. All data were checked for normality using the Shapiro–Wilk test. Dependency of MFR and caffeine ingestion was determined using a 2-way ANOVA, with $P$ values less than 0.05 being considered significant. Regressional analyses between plasma caffeine concentration and ingested caffeine were obtained for both sexes.

RESULTS

Study Population

A total of 40 volunteers underwent 4 serial PET/CT scans within 27 d (IQR = 17; 36). The volunteers had a median age of 23 y
(IQR = 22; 25), and 19 (47.5%) were women. Average body mass index of the volunteers was 22.7 ± 3.2 (women = 21.9 ± 3.1, men = 23.5 ± 3.0, P = 0.08). The median habitual daily coffee consumption was 2 cups (IQR = 1.5; 3) (women = 2, IQR = 1.5; 3 and men = 2, IQR = 1.5; 3, P = 0.59) per day, representing a median caffeine intake from coffee of 200 mg/d (IQR = 150–300).

Of the 40 volunteers, 1 volunteer (man) was excluded due to failure to comply with the protocol. In addition, 4 scans were excluded because of significant deviation from the criteria. Differences were considered significant for P < 0.05.

Rest MBF

Rest MBF assessments are shown in Figure 2. Significant differences in the rest MBF assessments for the 2 sexes were observed for MPI sessions with plasma caffeine concentrations ≤ 1 mg/L (P < 0.001) (no caffeine ingested) and ≥ 5 mg/L (P = 0.027) (caffeine ingested). Reduced heart rates were observed in the women after ingestion of caffeine whereas men had stable heart rates (Table 1). Similar test–retest repeatability coefficients were reported for the men and women (16.1% and 13.5% [P = 0.42], respectively) (Table 2). Women had higher diastolic pressure than men (62.3 ± 6.4 vs. 59.7 ± 7.8 mm Hg, P = 0.02) whereas lower systolic blood pressure was reported for women (104.6 ± 12.1 vs. 112.3 ± 12.4 mm Hg, P < 0.001) (Tables 3 and 4). No difference in RPP was observed between the 2 sexes (RPP rest: 6,394 ± 1,400 vs. 6,481 ± 1,488 [P = 0.72]) (Table 5). At rest, men had increased CVR when compared with women (Table 6).

Stress MBF

Women had higher heart rate and diastolic blood pressure, whereas systolic blood pressure was decreased when compared with men (heart rate: 85.1 ± 16.8 vs. 76.2 ± 18.0 beats per minute, diastolic blood pressure: 63.9 ± 9.1 vs. 57.3 ± 8.8 mm Hg, systolic blood pressure: 103.6 ± 12.1 vs. 109.4 ± 12.3 mm Hg, all P < 0.005) (Tables 1, 3, and 4). No difference was observed for RPP in women and men (8,833 ± 2,098 vs. 8,318 ± 2,155, P = 0.14, Table 5).

Increased stress MBF assessments were reported for women when compared with men (stress MBF [mL/g/min]: women vs. men [plasma caffeine concentration < 1 mg/L, no caffeine ingestion]: 3.3 ± 0.6 vs. 2.7 ± 0.7, [plasma caffeine concentration ≥ 1 mg/L, caffeine ingestion]: 3.0 ± 0.8 vs. 2.1 ± 1.0, both P < 0.001) (Fig. 3). Similar test–retest repeatability coefficients were reported for the men and women (18.4% and 10.9% (P = 0.29), respectively) (Table 2). Significant changes in the hemodynamic response were observed for the men. In contrast, consistent stress MBF assessments were observed for women at plasma caffeine concentrations below 5 mg/L (Fig. 3). Corresponding to the change in the hemodynamic response, CVR was observed to increase for men even at low plasma caffeine concentrations, whereas no changes in CVR were observed for women (Table 6). Linear correlations between ingested caffeine and plasma concentrations of caffeine in both men and women were observed (Fig. 4). Increased plasma caffeine concentrations were measured in women compared with men for the same doses of ingested caffeine. Furthermore, an almost 3-fold increase in the sensitivity to caffeine was observed in men, with consequential reductions in the stress MBF assessments (EC50 [mg/L]: men ≈ 3, women ≈ 8) (Fig. 5). Multivariable analyses including stress MBF, sex, and plasma caffeine concentrations revealed that both caffeine plasma concentration (P < 0.001), sex (P < 0.001), and

the interaction of the 2 (P = 0.049) had a significant impact on stress MBF assessments.

**MFR**

Comparable MFR assessments were observed for women and men (Fig. 6), with similar repeatability coefficients for the 2 sexes (women = 12.9%, men = 20.6% [P = 0.21]) (Table 2). However, MFR was reduced in men when plasma caffeine concentrations exceeded 5 mg/L, whereas women had stable MFR at all plasma caffeine concentrations (Fig. 6). On an individual basis, MFR might be reduced even at plasma concentrations as low as 1.2 mg/L in men and 7.1 mg/L in women. Multivariable analyses including MFR, sex, and plasma caffeine concentrations revealed that sex and caffeine plasma concentration (both P < 0.001), as well as the interaction of the 2 (P = 0.049), had a significant impact on the MFR assessments.

**DISCUSSION**

In this randomized controlled crossover trial, we evaluated the impact of plasma caffeine concentrations on stress MBF and MFR assessments in healthy volunteers. The main finding was a sex-specific response in stress MBF and MFR assessments when the volunteers had stress perfusion imaging after caffeine consumption. Multivariable analyses of the data revealed that sex, caffeine concentration, and the interaction of the 2 were strongly associated with changes in stress MBF and MFR. Hence, in healthy volunteers, caffeine intake was associated with a different hemodynamic response in men and women with consequential differences in the stress MBF and MFR assessments. Men were found more sensitive to caffeine concentration, where plasma caffeine concentrations as low as 1.2 mg/L might affect the perfusion estimates compared with 7.1 mg/L in women.

PCC = plasma caffeine concentration.
the estrogenic effect on the vascular tone (17). Several studies have shown an evident trend for higher plasma caffeine and lower plasma paraxanthine (the most active caffeine metabolite) concentrations in women as compared with men, suggesting that women metabolize caffeine slower than men. Women with higher estrogen levels have been reported to have decreased cytochrome P450 1A2 enzyme activity and decreased caffeine clearance (18). Furthermore, a study has reported that women have 25% higher adenosine A1A (at messenger RNA level) receptor and 40% lower A2A receptor expression (at messenger RNA level) than men and ovariectomized women (19). Thus, one can speculate that the differences in antagonistic potency of caffeine observed between men and women in our study is partially attributed to sex-related expression, adenosine receptor reserve, and intracellular signaling. However, the mechanism(s) involved are likely to be more complex and need to be scrutinized in future studies.

Stress MBF and MFR were observed to fluctuate for the women at different plasma caffeine concentrations. These effects may be caused by the low number of measurements obtained for the plasma caffeine concentrations ranging between 1 and 5 mg/L and, thus, statistical noise. The general reduction in stress MBF for scans obtained after caffeine consumption reported for the male volunteers was in concurrence with previous studies (5,7,16). Test–retest repeatability was tested for the baseline scans for all subjects with concurrent plasma caffeine concentrations < 1 mg/L. In this context, test–retest repeatability was found in concordance with previous studies evaluating the short-term variation in rest MBF (15). The concurrent test–retest repeatability measures, therefore, suggest that reductions in the MBF and MFR assessments observed for high plasma caffeine concentrations were introduced by the ingestion of caffeine. This finding is supported by the observed physiologic responses to caffeine ingestion. In concordance with previous studies, women had greater increases in diastolic blood pressure after caffeine administration than men (Table 3) (20,21). One explanation for this effect may be men have a more sensitive baroreflex than women (20,21). Further, sex differences in hemodynamic response to caffeine may be related to sex steroid hormone concentrations (22–24).

PCC = plasma caffeine concentration.
taken together, these studies suggest that men are more responsive to caffeine than women, a hypothesis supported by the findings in this study since caffeine had a greater potency in reducing stress MBF in men than women (Fig. 5). Caffeine competitively blocks all adenosine receptors (A1, A2A, A2B, A3), resulting in a compensatory increase in adenosine concentration, which in turn stimulates circulating chemoreceptors and other receptors (25). In adult mammals, it has been suggested that A2A receptors are implicated in O2 sensing by carotid glomus cells (chemoreceptors) and are involved in the transduction mechanisms of O2 sensing in carotid bodies. Therefore, excessive adenosine can activate chemoreceptors via binding to A2A receptors located in carotid bodies, thereby increasing sympathetic outflow of catecholamines leading to an increase in vascular resistance, and renin secretion (26). In this study, CVR was found to increase in men when the plasma caffeine concentration increased, whereas women had no significant changes in the CVR after ingestion of caffeine (Table 6). Sex differences in the clearance of plasma-protein-binding and differences in the volume of distribution may also explain some of the differences in the perfusion response to caffeine between sexes (27). Regional conditions favor regadenoson and dipyridamole over adenosine as the drugs of choice. Although only adenosine was evaluated in this study, it is likely that our findings can also apply to regadenoson and dipyridamole.

**Study Limitations**

This study was conducted in healthy young volunteers with normal cardiac perfusion without perfusion defects, and we cannot rule out that results would have differed in the typical patient population undergoing cardiac 82Rb PET testing. Patient populations are often elderly and have an intermediate likelihood of ischemic heart disease in addition to lower sex hormone concentrations, caffeine pharmacokinetics, and pharmacodynamics. Combined, these differences might cause different hemodynamic responses than those reported in this study. However, we find that an establishment of sex-specific data in young normal volunteers is important before investigating the impact of caffeine consumption in an elderly cohort in whom comorbidities and coronary artery disease are common. Another limitation is that our study was conducted in a single center using only 1 imaging system, which might affect the overall MBF and MFR assessments.

**CONCLUSION**

In healthy volunteers, we found that caffeine consumption before MPI affected men and women differently. Associations between plasma caffeine and significant reductions in stress MBF and MFR were found at lower plasma caffeine concentrations in men than in women.
No potential conflict of interest relevant to this article was reported.

**KEY POINTS**

**QUESTION:** Does caffeine before stress MPI affect the hemodynamic response differently in women and men?

**PERTINENT FINDINGS:** Caffeine consumption affects the hemodynamic response at a lower plasma caffeine concentration in men than women, with the stress MBF being affected with plasma concentrations of 1.2 mg/L in men as compared with 7.4 mg/L in women. The dose–response of caffeine plasma concentration and obtained stress MBF assessments revealed significantly increased sensitivity to caffeine in men when compared with women.

**IMPLICATIONS FOR PATIENT CARE:** Caffeine consumption less than 12 h before MPI sessions might lower the stress MBF assessments. At comparable plasma caffeine concentrations, men obtained stress MBF assessments revealed significantly increased sensitivity to caffeine in men when compared with women.
