Running title: Nuclear medicine in benign thyroid disease
ABSTRACT

Goiter, an enlargement of the thyroid gland, is a common endocrine abnormality. Constitutional factors, genetic abnormalities, and/or dietary and environmental factors may contribute to the development of nodular goiter. Most patients with non-toxic nodular goiter are asymptomatic or have only mild mechanical symptoms (“globus pharyngis”). Work-up of these patients includes measurement of TSH, fT3, fT4, thyroid auto-antibodies, ultrasound imaging, thyroid scintigraphy, and fine-needle aspiration biopsy of nodules with certain ultrasound and scintigraphic features. Treatment for multinodular goiter includes dietary iodine supplementation, surgery, radioiodine therapy (to decrease thyroid size), and mini-invasive ablation techniques.

Hypothyroidism ranges from rare cases of myxedema to more common mild forms (subclinical hypothyroidism). Primary hypothyroidism often has an autoimmune etiology. Clinical presentations differ in the neonate, children, adults and elderly patients. Work-up includes thyroid function tests and ultrasound imaging. Nuclear medicine is primarily used to locate ectopic thyroid tissue in congenital hypothyroidism, or to detect defects in iodine organification with the perchlorate discharge test. Treatment consists of thyroid replacement therapy with L-Thyroxine, adjusting the daily dose to the individual patient’s metabolic and hormonal requirements.

Subacute thyroiditis is a self-limited inflammatory disorder of the thyroid gland, often associated with painless or painful swelling of the gland and somatic signs/symptoms. Inflammation disrupts thyroid follicles resulting in a rapid release of stored T4 and T3 causing an initial thyrotoxic phase – often followed by transient or permanent hypothyroidism. Although subacute thyroiditis is often related to a viral infection, no infective agent has been identified. Subacute thyroiditis may be caused by a viral infection in genetically predisposed individuals. Work-up includes lab tests, ultrasound imaging, and radionuclide imaging. Thyroid scintigraphy demonstrates different findings depending on the phase of the illness, ranging from very low-to-absent tracer uptake in the thyroid gland in the hyperthyroid phase, to normal appearance in the late recovery phase. Since subacute thyroiditis is self-limited, treatment is directed toward relief of pain. High-dose nonsteroidal anti-inflammatory drugs are usually the first-line treatment. If severe pain persists, a course of corticosteroids may be necessary. Permanent hypothyroidism develops in up to 15% of patients with subacute thyroiditis, even more than 1 year following presentation.

Key Words: diffuse and nodular goiter; primary autoimmune hypothyroidism; subacute, destructive thyroiditis; lab tests for benign thyroid disorders; ultrasound imaging; radionuclide imaging; fine-needle aspiration biopsy; therapy of diffuse and nodular goiter; therapy of hypothyroidism; therapy of subacute thyroiditis
GOITER AND THYROID NODULES

Epidemiology and Clinical Presentation

Goiter, an enlargement of the thyroid gland (>20 mL in men and >15 mL in women) with or without nodules, is one of the most common endocrine abnormalities. If thyroid function is normal, it is described as non-toxic nodular goiter. The incidence of new nodular goiter (NG) cases in adults in the US is 0.1–1.5% of the general population per year (1). Goiter is more common in women than men (2). In areas of iodine deficiency the incidence of thyroid nodules increases with age (without gender-related difference) (3), whereas in iodine-sufficient areas the prevalence of NG decreases with age (4). Constitutional factors, genetic abnormalities, and/or dietary/environmental factors may contribute to the development of NG (2-5). Thyroid nodules may become autonomous, possibly evolving to cause thyrotoxicosis.

Clinically, goiter is categorized into diffuse, solitary nodular, or the most prevalent phenotype, multinodular goiter. Most patients with non-toxic nodular goiter are asymptomatic or have mild mechanical symptoms (“globus pharyngis”). Nodular goiter is often discovered incidentally during an ultrasound scan performed for other reasons. Symptoms of compression of the trachea, esophagus, great vessels, and recurrent laryngeal nerve in the presence of a goiter suggest that a long-term NG has partially migrated to the retrosternal and/or upper mediastinal regions.

Etiology and Pathophysiology

Worldwide the most important environmental factor for goiter development is iodine deficiency (2,3,6), and there is an inverse correlation between iodine intake and the prevalence of goiter (7). Other factors include genetic susceptibility, female gender, increased body mass, and smoking (6,8,9). Smoking promotes goiter development probably due to thiocyanate in cigarette smoke, which block iodination, leading to a compensatory increase in secretion of the thyroid-stimulating hormone (TSH) (10).

Lab Tests

TSH, free T4 (fT4) and free T3 (fT3) should be measured. If the TSH is reduced and fT4 and/or fT3 are elevated, the patient has progressed to a toxic nodular goiter. In iodine-deficient areas, nodules may become autonomous because of persistent stimulus from elevated TSH due to reduced thyroid hormone production.
The presence of antibodies recognizing thyroid-peroxidase (TPO-Ab), thyroglobulin (Tg-Ab), and/or the TSH-receptor suggests the coexistence of Hashimoto’s disease or Graves’ disease.

Ultrasound Imaging

Ultrasonography is used to determine thyroid volume and the echogenicity, margins, shape, content, calcifications, vascularity, size, and elasticity of nodules in addition to the status of regional lymphnodes (Fig. 1 and Supplemental File-1). The European Thyroid Association (11), the American College of Radiology (12), and the American Thyroid Association (ATA) (13) have issued guidelines (with slight differences) for stratifying the risk of malignancy of thyroid nodules according to the so-called “thyroid imaging reporting and data system” (TI-RADS). The ultrasound-based criteria (Tables 1 and 2) stratify thyroid nodules into five categories of risk for malignancy, a change from prior consensus guideline that stratified the ultrasound risk of malignancy into three categories (14); examples of thyroid nodules with different EU-TIRADS scores are presented in Supplemental File-2. About 50% of the nodules can be classified as benign by ultrasound criteria alone, and nodules with low-risk features have a false negative risk of only 0.3% (11). It is still debated which TI-RADS version provides better outcome (15,16). Ultrasound guidance is crucial to localize sites for fine-needle aspiration biopsy (FNAB) (17) and mini-invasive therapeutic procedures (18).

Fine-needle Aspiration Biopsy of Thyroid Nodules

The prevalence of thyroid cancer in patients referred for goiter evaluation is 4%–18% (19). FNAB should be performed in suspicious nodules with high-risk ultrasound features, especially if combined with the scintigraphic features described further below. Table 3 summarizes the main features of the two most widely employed systems for classifying the cytology findings according to the risk of malignancy, the Bethesda system and the British Thyroid Association (BTA) system. Approximately 20% of FNABs of thyroid nodules have indeterminate cytology (Bethesda III, or BTA Thy3a-f), with a rate of malignancy of 10%–30% (20). Molecular testing for gene mutations (e.g., BRAF, RAS, RET/PTC, PPARγ) enhances the accuracy of FNAB in nodules with indeterminate cytology (21,22).

Diagnostic and Therapeutic Radionuclide Procedures

*Thyroid Scintigraphy with $^{123}$I-Iodide or $^{99m}$Tc-Pertechnetate.* Thyroid scintigraphy provides a map of functioning thyroid parenchyma (Fig. 2), including hypofunctioning nodules (“cold” areas on the scan) or autonomously functioning nodules (“hot” areas on the scan, with variable uptake in the extra-nodular thyroid parenchyma – up to complete suppression). Combined with ultrasonography,
thyroid scintigraphy can determine which thyroid nodules should be characterized with FNAB (23). Nodules that appear as “warm/hot” on thyroid scintigraphy are rarely malignant (24); therefore, FNAB of such lesions is not indicated (Fig. 3).

In areas with sufficient dietary iodine intake, thyroid scintigraphy is not necessary in patients with diffuse or (multi)nodular goiter when serum TSH is normal, because all such nodules usually appear as cold areas on the scan and should be evaluated with FNAB if exhibiting a high TI-RADS score and exceeding 10 mm in any diameter (25,26). However, in iodine-deficient areas the serum TSH level alone may not be sufficient to exclude the presence of autonomously functioning thyroid nodules (27), and thyroid scintigraphy should be performed in all patients with nodular goiter. A meta-analysis showed a 50% prevalence (95% CI: 32%–68%) of normal TSH values in patients with autonomously functioning thyroid nodule(s) (28).

**PET/CT with 18F-FDG in Patients with Nodular Goiter.** “Incidentalomas” – when an 18F-FDG PET/CT scan performed for reasons not related to the thyroid (usually in patients with non-thyroid cancers) shows increased tracer uptake in the thyroid gland – as it occur in 1%–2% of all 18F-FDG scans. Two patterns of 18F-FDG uptake have been observed, diffuse and focal (Fig. 4). Diffuse 18F-FDG uptake in the thyroid gland is usually associated with autoimmune thyroiditis and has little or no clinical relevance (29-31). Focal 18F-FDG uptake in the thyroid gland can be found in nodular goiter, and about 35% of these “incidentalomas” are thyroid cancer (32). Therefore, these cases should be further investigated for unequivocal characterization (33). The occurrence of thyroid incidentalomas during a PET/CT scan is not unique to 18F-FDG, as they can be observed also with other PET tumor imaging agents, e.g. 18F-fluorocholine, 68Ga-DOTA-TOC, and 68Ga-PSMA-ligand (34-36) (Fig. 5).

18F-FDG-avid thyroid nodules that cannot be classified with FNAB cytology are more likely to be malignant than a nodule without enhanced [18F]FDG uptake (Fig. 6); whereas, a similar thyroid nodule without increased [18F]FDG uptake is highly unlikely to be malignant (37-39). Although any focal [18F]FDG uptake above the normal thyroid background is interpreted as positive and a high SUVmax increases the risk of malignancy (38,40), no specific SUVmax threshold has been identified to reliably discriminate malignant from benign thyroid nodules.

**Therapy of Nodular Goiter**

*Surgery.* Compressive symptoms are a major indication for surgery, as stated by the ATA and by the German Society for General and Visceral Surgery (41).
Radioiodine Therapy for Reduction of Goiter Volume. In patients with either diffuse or nodular goiter with mechanical symptoms, who cannot undergo surgery because of comorbidities (42), can be treated with radioiodine. A practical approach to determine the activity to be administered is based on the assumption of a target activity of 3.7 MBq (100 µCi) of radioiodine per gram of functioning thyroid tissue 24 h after administration. The initial estimate (i.e. 3.7 MBq × volume of functioning thyroid tissue as assessed by thyroid scintigraphy) is corrected by the 24-h radioiodine uptake (RAIU) value. More personalized dosimetry-based approaches to determine the activity of radioiodine for therapy (43) have been discussed in the companion CE article (44). Whereas in Graves’ disease the target absorbed dose necessary to ablate hyperfunctioning thyroid tissue is between 200–400 Gy, data derived from external beam radiation therapy for cancers of the head and neck suggest that an absorbed dose between 100–150 Gy is sufficient for tissue ablation of normal thyroid parenchyma (45,46).

This treatment causes an average 30%–40% volume reduction within one year post-treatment, with further reduction up to 50%–60% of the initial thyroid volume/mass in the following year (42). To increase radioiodine uptake in multinodular glands, an off-label use of recombinant human TSH (rhTSH), administered i.m. as a single 0.3 mg dose 24 h before radioiodine therapy, has been suggested (47-51). An advantage of pre-treatment with rhTSH is that the activity of administered radioiodine is reduced by about half the activity that should be administered without rhTSH pre-treatment – with consequent reduction in overall radiation dosimetry (52,53).

Besides the usual contraindication in pregnant/lactating women, some conditions must be fulfilled before submitting patients to this treatment:

- Evaluation for malignancy (ultrasonography, thyroid scintigraphy, and FNAB if necessary) must be performed prior to radioiodine therapy.
- The total thyroid volume/mass must be evaluated for bulky goiters extending to the upper mediastinum (which may include MRI, or CT without contrast agent).
- The “active” thyroid volume/mass should be evaluated by thyroid scintigraphy, considering that cystic lesions and other low-uptake areas are not expected to respond to radioiodine therapy.

Since most patients treated with radioiodine develop hypothyroidism within 2–3 years after therapy, all patients receiving radioiodine therapy should be followed with semi-annual serum TSH assays (42,54).

Medical Therapy of (Nodular) Goiter
Once their benign nature has been established, goiters with small nodules usually do not require treatment and can safely be monitored with regular follow-up. Since iodine deficiency has a key role in thyroid enlargement, iodine supplementation may reduce goiter size (55,56).

Historically, TSH-suppressive therapy with L-Thyroxine was used with the aim of reducing stimulation of thyroid parenchyma and nodules. Although this approach was widely embraced in the past (56-59), the long-term outcomes of this approach are still controversial (59). Current ATA guidelines do not recommend the routine use of L-Thyroxine for the treatment of benign thyroid nodules (13), although it may remain a feasible option for young patients in case of mild iodine deficiency (59,60).

**Mini-invasive Treatments for Nodular Goiter**

Tissue “ablation” techniques have been developed to induce necrosis/apoptosis of specific thyroid nodules. Recent mini-invasive techniques induce thermal ablation with different forms of energy such as microwaves, radiofrequency, high-intensity focused ultrasound, or laser energy (13).

---

**HYPOTHYROIDISM**

**Epidemiology and Clinical Presentation**

Hypothyroidism is a systemic condition caused by transient or permanent: i) thyroid failure (primary hypothyroidism); ii) deficiency of thyrotropin secretion (TSH) (secondary, or central hypothyroidism); or iii) resistance of peripheral target tissues (Supplemental File-3).

The spectrum of hypothyroidism ranges from severe overt hypothyroidism (myxedema) to milder forms, subclinical hypothyroidism. Primary hypothyroidism accounts for 95%–99% of thyroid failure and has usually an autoimmune etiology. Deficiency of pituitary or hypothalamic function (secondary or tertiary hypothyroidism), and peripheral resistance to thyroid hormones, or their inactivation due to auto-antibodies, are rare.

The prevalence of hypothyroidism in the US (defined as TSH levels >4.5 mIU/L) is 3.7% of the general population (61). In Europe it is 0.65% (95% CI: 0.38%–0.99%) for overt and 4.11% (95% CI: 3.05%–5.31%) for subclinical hypothyroidism (62).

*Congenital hypothyroidism.* Congenital hypothyroidism is the most frequent congenital endocrine disorder (1:2.200–2.500 live births). Delayed diagnosis leads to growth retardation and severe neurological and psychiatric impairment.
Children and Adolescent Hypothyroidism. Hypothyroidism in children and adolescents is characterized by retarded growth and short stature, variable but usually declining school performance, and signs/symptoms similar to those occurring in adults. In addition to the history and physical examination, laboratory evaluation should include TSH, fT4 and fT3. In the presence of abnormal findings, the patient should be referred to a pediatric endocrinologist.

Hypothyroidism in Adults. Thyroid hormone deficiency reduces function in almost every organ system depending on the degree of hypothyroidism (Table 4).

Hypothyroidism in the Elderly. The most frequent signs/symptoms are fatigue, muscle weakness, cold intolerance, dry skin, hair loss, constipation, poor appetite, depression and/or mental deterioration, hearing loss, cardiomegaly and congestive heart failure.

Drug-Induced Hypothyroidism. The large amount of iodine released from amiodarone (an iodine-rich drug used for treating tachyarrhythmias) may fail to escape the Wolff-Chaikoff effect (see below) and thus cause iodine-induced hypothyroidism, especially in patients with preexisting autoimmune thyroiditis (63,64). Lithium therapy may cause hypothyroidism by blocking both release and synthesis of thyroid hormones (65). Interferon may precipitate hypothyroidism, either by aggravating preexisting autoimmune thyroiditis and/or by a direct cytotoxic effect on thyroid follicular cells (66). Tyrosine kinase inhibitors (TKI) may induce hypothyroidism by mechanism(s) not fully understood (67).

Pathophysiology

The most frequent cause of hypothyroidism in adults is autoimmune thyroiditis (Ord-Hashimoto disease). It most probably results from a combination of a predisposing genetic background with exogenous and endogenous factors (68). Infiltration of thyroid tissue by amyloidosis, hemochromatosis, sarcoidosis, cystinosis, scleroderma, or leukemia may also cause hypothyroidism and goiter.

Hypothyroidism may result from either severe iodine deficiency or iodine excess. In severe iodine deficiency, large goiters and variable degrees of hypothyroidism may be observed at any age. Excess iodine intake (>1–2 mg/day) acutely inhibits iodine organification and thyroid hormone synthesis (Wolff-Chaikoff effect) as well as thyroid hormone release. In most euthyroid subjects iodine excess does not cause hypothyroidism due to an adaptive mechanism (escape, usually at ~10 days after iodine loading); nevertheless, patients with preexisting thyroid abnormalities may fail to escape the Wolff-Chaikoff effect and thus develop hypothyroidism.
Iatrogenic hypothyroidism can be observed following treatment of hyperthyroidism with antithyroid drugs or radioiodine, as well as after total thyroidectomy or external beam radiation therapy of the head and neck region.

**Lab Tests**

*TSH.* Primary hypothyroidism is characterized by increased TSH and decreased FT4; in subclinical hypothyroidism TSH is increased (generally between 5–10 mIU/L) and FT4 is normal. In central hypothyroidism low FT4 is associated with low-to-inappropriately normal TSH.

*Antibodies.* Thyroid peroxidase antibodies (TPO-Ab) and thyroglobulin antibodies (Tg-Ab) are positive in most patients with autoimmune thyroiditis.

*Lipids.* In both overt and subclinical hypothyroidism the lipid profile shows increased total LDL cholesterol levels with increased or normal HDL levels. Triglyceride levels are normal or slightly elevated.

**Ultrasound Imaging**

In hypothyroidism the thyroid volume can be normal, increased (goiter) or reduced (atrophic form of chronic autoimmune thyroiditis, hypoplasia or hemiagenesis) (Supplemental File-4). Inhomogeneous hypoecogenicity is typical of chronic autoimmune thyroiditis. Ultrasonography can also identify ectopic thyroid tissue in congenital hypothyroidism.

**Radionuclide Techniques in Hypothyroidism**

Nuclear medicine currently has a limited role in hypothyroidism, since the diagnosis is based on signs/symptoms and on thyroid hormonal profile (TSH, fT3, fT4). The only current application of radionuclide imaging in hypothyroidism concerns congenital hypothyroidism (69). Thyroid scintigraphy with either $^{99m}$Tc-Pertechnetate or preferably $^{123}$I-Iodide constitutes the best standard for ascertaining thyroid agenesis or locating ectopic thyroid tissue in the mediastinum, or base of the tongue – especially in newborns/children.

When the thyroid gland is in its normal location in a patient with congenital hypothyroidism, the cause of hypothyroidism can be genetic mutation(s), over 25 of which have been described (70,71). The perchlorate discharge test explores defects in the intrathyroidal organification process of iodide as a cause of congenital hypothyroidism. Once iodide is “trapped” in the thyroid gland following active transport mediated by sodium/iodide symporter (NIS), iodine binds to thyroglobulin – therefore no longer requiring active transport for intracellular retention. Perchlorate ions inhibit NIS-mediated iodide transport and cause loss of iodide not bound to thyroid hormones. Evaluating the release of
radioiodine caused by perchlorate allows evaluation of non-organified intrathyroidal iodide and thus assessment of an iodide-binding defect (69).

**Thyroid Replacement Therapy in Hypothyroidism**

Approximately 85 µg of L-Thyroxine is secreted by the thyroid gland daily. Of the total daily T3 production (about 33 µg in normal man), approximately 80% arises from peripheral conversion from T4, and only about 20% derives from direct thyroidal secretion. Synthetic L-Thyroxine is recommended as the preparation of choice to treat hypothyroidism, due to its efficacy, favourable side-effect profile, ease of administration, good intestinal absorption, long serum half-life, and low cost. L-Thyroxine is converted in-vivo into its active metabolite T3. Nevertheless, a subgroup of hypothyroid patients are not satisfied with L-Thyroxine therapy alone (72); in these patients, combination therapy with L-Thyroxine and Liothyronine (L-T3) might be considered (73,74).

Hypothyroid patients with minimal endogenous thyroid function require L-Thyroxine doses of 1.6–1.8 µg/kg of body weight (ideal body weight being a better predictor than actual body weight). Patients with L-Thyroxine dose requirements much higher than expected should be evaluated for gastrointestinal disorders such as *Helicobacter pylori*-related gastritis, atrophic gastritis, celiac disease, lactose intolerance, and intestinal giardiasis. Serum TSH monitoring is advisable when starting medications such as phenobarbital, phenytoin, carbamazepine, rifampin, and sertraline.

Symptoms, such as cold intolerance or dry skin lack sensitivity and specificity, therefore are not recommended for judging adequacy of replacement in the absence of biochemical assessment. About 6-8 weeks after a change in L-Thyroxine dosage Serum TSH should be checked.

**SUBACUTE THYROIDITIS**

Subacute thyroiditis is a self-limited inflammation of the thyroid gland, often associated with painless or painful swelling of the gland and somatic signs/symptoms including fever and malaise (75). Painless subacute thyroiditis may be overlooked or misdiagnosed, especially when occurring in the post-partum – occasionally related to postpartum psychosis or depression (76).

Originally described in 1895 by Mygind as “thyroiditis akuta simplex” (77), the pathology of subacute thyroiditis was first depicted in 1904 by the Swiss surgeon Fritz de Quervain, whose name is associated with the disorder. The inflammatory process causes disruption of thyroid follicles resulting
in a rapid release of stored T4 and T3 causing an initial thyrotoxic phase – often followed by transient or permanent hypothyroidism.

**Epidemiology and Clinical Presentation**

The incidence of subacute thyroiditis is 4.9/100,000 per year (78). Its prevalence is highest in middle-aged women (female:male ratio between 4:1–7:1). Subacute thyroiditis often occurs after an upper respiratory viral illness – thought to trigger the disease.

Anterior neck pain is the cardinal feature of de Quervain’s subacute thyroiditis. The inflammation can start in one lobe and then migrate to the contralateral lobe. Dysphagia is occasionally reported. The gland is firm and tender on palpation. In the early phases there can be signs of thyrotoxicosis (tachycardia, tremor, increased skin warmth), sometimes requiring the use of a beta-blocker. The thyrotoxic phase may be followed by hypothyroidism that is usually transient, although it can occasionally be permanent. In patients with hypothyroid symptoms, L-Thyroxine replacement should be started – with frequent TSH monitoring to assess possible tapering or continuation of replacement therapy.

**Etiology and Pathophysiology**

Although subacute thyroiditis has been related to a viral infection (79), so far no infective agent has been clearly identified (80). The destructive events of subacute thyroiditis may trigger thyroid autoimmunity in subjects with a genetic background, occasionally resulting in chronic autoimmune thyroiditis with hypothyroidism (81), or in Graves’ disease (82).

About 72% of patients with subacute thyroiditis present the HLA-BW35 antigen (83), and familial subacute thyroiditis can be associated with HLA-B35 (84), suggesting that the disease may be caused by a viral infection in genetically predisposed individuals. Therapies potentially affecting the immune system may be associated with subacute thyroiditis (85), as in patients with chronic hepatitis B or C treated with interferon and/or ribavirin (66).

**Lab Tests**

Laboratory exams show a moderate leukocytosis, elevated erythrocyte sedimentation rate, and elevated serum C-reactive protein levels. In the thyrotoxic phase, suppressed serum TSH is associated with normal or elevated free T3 and free T4. The thyrotoxic phase typically lasts four to eight weeks. Thyroglobulin levels are elevated because of the destruction of thyroid follicles.
Ultrasound Imaging

Thyroid ultrasound shows heterogeneous, diffuse, hypoechoic and confluent areas, with no increase in the vascularity on color Doppler (86). These abnormalities often revert to a near-normal pattern when the condition resolves (Fig. 7).

Radionuclide Imaging

Thyroid scintigraphy is characterized by very low-to-absent tracer uptake in the thyroid gland in the thyrotoxic phase – a pattern shared by other conditions of destructive thyroiditis (e.g, type-2 amiodarone-induced thyroid dysfunction). Depending on the phase of the illness, there can be absent tracer uptake in the whole gland or in part of the gland. Even when subacute thyroiditis affects primarily one lobe of the thyroid, the scan may show completely absent tracer uptake in the whole gland (Fig. 7), because of suppressed TSH levels due to a thyrotoxic phase of the disease.

Therapy of Subacute Thyroiditis

Since subacute thyroiditis is self-limited, in most cases the thyroid gland spontaneously resumes normal thyroid hormone production. Treatment is directed toward relief of thyroid pain. High-dose nonsteroidal anti-inflammatory drugs are usually the first-line treatment (75). If neck pain does not improve after a few days, or if the patient presents with severe neck pain, corticosteroids may be considered (80), which leads to improvement within two days. After 5–7 days of high-dose prednisone, the dose is tapered over the next 2–4 weeks. As the dose is tapered, most patients have no recurrence of symptoms, but occasionally this does occur and the dose must be increased again.

Thyroid hormone supplementation is generally not necessary for the transient hypothyroid phase of subacute thyroiditis, unless patients are symptomatic. However, permanent hypothyroidism develops in up to 15% of patients, even more than one year following presentation (75).

FIGURE 2. Thyroid scintigraphy (anterior view) acquired 15 min after IV injection of $^{99m}$Tc-pertechnetate in a patient with diffuse, non-nodular goiter and normal thyroid function, showing global hyperplasia of the thyroid with homogeneous tracer distribution within the gland. The right lobe is larger than the left, with a longitudinal axis measuring about 70 mm.
FIGURE 3. Thyroid scintigraphy in two patients with nodular goiter (anterior view). Left panel: $^{99m}$Tc-Pertechnetate scan acquired 15 min after IV injection, showing moderately enlarged gland with reduced tracer uptake in lower half of left lobe, corresponding to a palpable nodule (green broken line); in case of suspicious ultrasound features of this nodule, the patient should be referred for FNAB. Right panel: scan acquired with pinhole collimator 24 h after oral administration of 1.85 MBq $^{131}$I-iodide to a candidate for radioiodine therapy of multinodular goiter with autonomously functioning nodule(s); only the nodule at the apex of right lobe (red broken line) shows increased tracer uptake, whereas nodule at base of right lobe and at the isthmus (green broken lines) do not concentrate radioiodine (“cold” nodules); FNAB was performed because of intermediate-risk EU-TIRADS score, and showed both nodules to be benign.
FIGURE 4. Thyroid incidentalomas observed in 2 patients undergoing $^{18}$F-FDG PET/CT for thyroid-unrelated oncological conditions (top: axial fused PET/CT; bottom: whole-body MIP image). Yellow arrows indicate the unexpected findings of focally increased tracer uptake (left) and diffuse tracer uptake (right). While diffusely enhanced tracer uptake is generally associated with thyroiditis, any focal increase in tracer uptake must be further evaluated with ultrasound and possibly FNAB, because of the relatively high rate of thyroid malignancy.
**FIGURE 5.** Thyroid incidentalomas (yellow arrows) observed in 3 patients evaluated with PET tracers other than $^{18}$F-FDG for oncological conditions (top: axial fused PET/CT; bottom: coronal fused PET/CT). Left panel: a patient with biochemical recurrence of prostate cancer. Previously he had a left hemithyroidectomy because of nodular goiter; histology showed chronic autoimmune thyroiditis; diffusely enhanced $^{18}$F-fluorocholine uptake in residual right thyroid lobe corresponds to autoimmune thyroiditis. Center panel: focally increased $^{68}$Ga-PSMA11 uptake within multinodular goiter prevalent in left lobe. Right panel: focally increased $^{68}$Ga-DOTA-TOC uptake in right thyroid lobe [courtesy of Drs. Paola A. Erba and Roberta Zanca, Regional Center of Nuclear Medicine, University of Pisa, Pisa, Italy].
FIGURE 6. Evaluation of 30-y-old woman with family history of familial papillary thyroid carcinoma. Ultrasonography (A: axial view; C: longitudinal view) shows a 25-mm mixed iso-hypoechoic solid nodule of right lobe, with microcalcifications (small white arrow). Serum calcitonin was undetectable, and TSH was 2.7 µIU/mL; FNAB showed high-risk undetermined lesion (BTA Thy3f). $^{18}$F-FDG PET/CT showed intense focal uptake ($SUV_{\text{max}}$ 12) in thyroid nodule of right lobe (B: coronal fused image). An additional focus of increased $^{18}$F-FDG uptake (D: coronal fused image) was noted in a deeper plane, corresponding to a small lymph node of the central compartment not detected at ultrasonography. The patient underwent thyroidectomy and lymph node dissection of the central compartment, which revealed a BRAF-mutated papillary thyroid carcinoma with multiple lymph node metastases [courtesy of Dr. Arnodo Piccardo, Nuclear Medicine Department, “Galliera” Hospital, Genoa, Italy].
FIGURE 7. Ultrasound and scintigraphy images of a 46-y-old woman with subacute thyroiditis arising in a pre-existing chronic autoimmune thyroiditis. At presentation the patient had a tender goiter and pain whilst swallowing, but no fever. Abnormally increased leukocyte count and ESR, but normal PCR. TSH level 0.01 mIU/L, with increased fT3 (almost 2-fold upper normal limit) and fT4 (1.5-fold upper normal limit). Left: ultrasound axial (top) and longitudinal views (bottom), showing markedly hypoechoic area in left thyroid lobe, with poorly defined margins. Center: anterior view 99mTc-Pertechnetate scintigraphy at presentation, showing minimal tracer uptake in the thyroid gland, with physiologic visualization of the parotid and submandibular salivary glands; the downward-pointing triangle indicates the sternal notch. Right: axial (top) and longitudinal views (bottom) of ultrasonography obtained one year later, showing almost complete recovery of the abnormalities observed in the baseline ultrasound scan. Thyroidal hormonal profile was completely normal at this time.

Ultrasonography of a diffuse, non-nodular goiter (axial view). Outline of the thyroid gland is indicated by the broken line. Inhomogeneous ultrasound pattern, without clear nodules but with isoechoic and hypoechogenic pseudonodules. TG: thyroid gland (right and left lobes). SDM: skin, dermis and muscles forming the superficial layer in the neck. TL: tracheal lumen. BV: major blood vessels of the neck.
Supplemental File 2: examples of different ultrasound scores of thyroid nodules according to EU-TIRADS criteria of the European Thyroid Association

Ultrasound features of thyroid nodules (indicated by open arrows) according to EU-TIRADS criteria. A) spongiform nodule; B) isoechoic solid nodule; C) mildly hypoechoic nodule; D) hypoechoic nodule with microcalcifications (small white arrow); E) hypoechoic nodule with taller-than-wide shape and extrathyroidal extension (small white arrow); F) markedly hypoechoic nodule with extrathyroidal extension (small white arrow). Cytology of nodules in A), B), and C) was consistent with benign (colloid) nodules, whereas nodules depicted in D), E), and F) were papillary thyroid carcinomas.
Supplemental File 3: Classification of Hypothyroidisms

Primary hypothyroidism

**Congenital**
- Thyroid dysgenesis
  - Aplasia; hypoplasia; ectopic gland
- Thyroid dyshormonogenesis
  - Sodium-iodide symporter defect; thyroid peroxidase defect; hydrogen peroxidase generation defects (DUOX2, DUOXA2 gene mutations); pendrin defect; thyroglobulin defect; iodicotyrosine deiodinase defect
- Resistance to TSH binding or signaling
  - TSH receptor defect; G protein defect (type 1A and 1B pseudo-hypoparathyroidism)

**Acquired**
- Thyroiditis
  - Autoimmune
    - Hashimoto’s thyroiditis (goiter and atrophic forms)
    - Painless and post partum thyroiditis (transient, rarely permanent)
    - Subacute thyroiditis (transient, rarely permanent)
- Thyroid infiltration
  - Amyloidosis; hemochromatosis; sarcoidosis
- Iodine deficiency; goitrogens in foodstuffs; pollutants
- Iodine excess
- Iatrogenic
  - $^{131}$I-iodide therapy
  - Surgery
  - External irradiation for nonthyroidal malignancy
  - Drugs
    - Antithyroid drugs (methimazole, carbimazole, propylthiouracil)
    - Amiodarone, lithium, iodide, interferon-α, tyrosine kinase inhibitors

Central hypothyroidism

**Congenital**
- Isolated TSH deficiency
- Congenital hypopituitarism (combined pituitary hormone deficiencies)

**Acquired**
- Pituitary (secondary) or hypothalamic (tertiary) disorders
- Bexarotene (retinoid X receptor agonist)
- Dopamine or severe illness

Peripheral congenital hypothyroidism
- Thyroid hormone cell membrane transport defect (MCT8 gene mutations)
- Thyroid hormone resistance (thyroid hormone receptor α e β gene mutations)
Supplemental File 4: examples of ultrasound patterns in hypothyroidism

Ultrasound patterns observed in hypothyroidism (axial views). Upper panel: chronic autoimmune thyroiditis, showing enlarged thyroid lobes with diffuse, moderate hypoechoicnicity and marked inhomogeneity. Middle panel: chronic autoimmune thyroiditis, showing the atrophic form. Lower panel: thyroid hemiagenesis, showing a normal right lobe and isthmus, but completely absent left thyroid lobe.
