ABSTRACT

Positron emission tomography (PET) radiomics applied to oncology allows the measurement of intra-tumoral heterogeneity. This quantification can be affected by image protocols hence there is an increased interest in understanding how radiomic expression on PET images is affected by different imaging conditions. To address that, this study explores how radiomic features are affected by changes in ^{18}F -FDG uptake time, image reconstruction, lesion delineation, and radiomics binning settings. **Methods:** Ten non-small cell lung cancer (NSCLC) patients underwent ^{18}F -FDG PET scans on two consecutive days. On each day, scans were obtained at 60min and 90min post-injection and reconstructed following EARL version 1 (EARL1) and with point-spread-function resolution modelling (PSF-EARL2). Lesions were delineated using thresholds at $\text{SUV}=4.0$, 40% of SUV_{max} , and with a contrast-based isocontour. PET image intensity was discretized with both fixed bin width (FBW) and fixed bin number (FBN) before the calculation of the radiomic features. Repeatability of features was measured with intraclass correlation (ICC), and the change in feature value over time was calculated as a function of its repeatability. Features were then classified on use-case scenarios based on their repeatability and susceptibility to tracer uptake time. **Results:** With PSF-EARL2 reconstruction, 40% of SUV_{max} lesion delineation, and FBW intensity discretization, most features (94%) were repeatable at both uptake times ($\text{ICC}>0.9$), 39% being classified for dual-time-point use-case for being sensitive to changes in uptake time, 39% were classified for cross-sectional studies with unclear dependency on time, 20% classified for cross-sectional use while being robust to tracer uptake time changes, and 6% were discarded for poor repeatability. EARL1 images had one less repeatable feature than PSF-EARL2 (*Neighborhood Gray-Level Different Matrix Coarseness*), the contrast-based delineation had the poorest repeatability of the delineation methods with 45% features being discarded, and FBN resulted in lower repeatability than FBW (45% and 6% features were discarded, respectively). **Conclusion:** Repeatability was maximized with PSF-EARL2 reconstruction, lesion delineation at 40% of SUV_{max} , and FBW intensity discretization. Based on their susceptibility to tracer uptake time, radiomic features were classified into specific NSCLC PET radiomics use-cases.

Key words: PET; Radiomics; Texture analysis; Repeatability; Dual-Time-Point

INTRODUCTION

^{18}F -2-Fluoro-2-deoxy-2-D-glucose (^{18}F -FDG) positron emission tomography/computed tomography (PET/CT) is an important technique for staging and treatment response evaluation of patients with non-small cell lung cancer (NSCLC). This evaluation can be achieved either visually or using standardized uptake values (SUV) and total lesion glycolysis measurements (1–5). However, these semi-quantitative approaches ignore possible tracer uptake heterogeneity within the tumor (6), overlooking potentially useful information. To address that, the field of *radiomics* measures textural information available in medical images, resulting in a more complete phenotyping of the tumor (7–9).

PET radiomics in oncology allows the extraction of several features characterizing tumor tracer uptake, shape, and intra-tumoral heterogeneity (10–13). This approach showed promising results, including lesion histological sub-type identification, aiding automated lesion delineation, and disease-free survival prediction (14–18). However, radiomic features are sensitive to several image settings, including PET acquisition and reconstruction, image noise, lesion segmentation method, and signal intensity discretization (11,19–26). This leads to difficulties in multi-center studies, possibly explaining the poor reproducibility of results that has raised skepticism on the usefulness of radiomics (9,19,27–31). Furthermore, these issues are amplified by the lack of negative publications on the field (32). Strategies have been developed to mitigate this variability, improving post-reconstruction harmonization of textural features (33–35).

One aspect of ^{18}F -FDG PET radiomics that has not been extensively explored is its uptake time dependence. The time between tracer injection and image acquisition alters the uptake in metabolically active regions where ^{18}F -FDG gradually accumulates, affecting SUV-related metrics and their repeatability (36–38). ^{18}F -FDG PET/CT textural analysis from dual-time-point static scans has been used to differentiate benign and malignant pulmonary lesions despite features presenting a wide range of accuracy (39,40). Time-related PET radiomics have been also explored as *dynamic features* (41). However, neither of these studies assessed how tracer uptake time could influence textural features repeatability.

Our hypothesis is that different features have different dependence on tracer uptake time and that this dependence may be influenced by image settings. Therefore, we evaluate how radiomic features (SUV-based and textural) are affected by tracer uptake time and whether its effects are smaller or larger than feature repeatability. Based on each feature's repeatability and dependence on tracer uptake time, features are classified for cross-sectional or single-injection dual-time-point use-cases. Several image settings are considered, including PET/CT image reconstruction algorithms, lesion delineation methods, and intensity discretization strategies.

MATERIALS AND METHODS

Dataset

Ten patients with confirmed stage IIIB or IV NSCLC underwent double baseline ^{18}F -FDG PET/CT scans on a Gemini TF scanner (Philips Healthcare, Cleveland, OH, USA), as previously described (5,20). Patients fasted for six hours or more, then a low-dose CT was acquired for attenuation correction followed by a whole-body ^{18}F -FDG PET scan 60 min after tracer injection. Thirty minutes later, a second whole-body PET and low-dose CT were performed. This procedure was repeated within three days of the first scan for test-retest measurements. All PET data were normalized and corrected for scatter and random events, dead time, attenuation, and decay. Two reconstruction protocols were used, one following the EARL version 1 guidelines (EARL1) and another with point-spread-function resolution modelling (PSF-EARL2) (42–44). PET images had a final resolution of $144 \times 144 \times 254$ with a voxel size of $4 \times 4 \times 4 \text{ mm}^3$. On the first day of scans, the average injected activity was 248MBq (range: 194–377MBq) and was 238MBq (192–392MBq) on the second day. The average post-injection start times on the first day were 61min (59–67min) and 92min (90–97min), and 60min (60–63min) and 90min (90–95min) on the second day. All patients gave written informed consent before enrolment and the study was approved by the Medical Ethics Review Committee of the VU University Medical Center (Dutch trial register [trialregister.nl] NTR3508).

Radiomic Feature Extraction

Lesion delineation and radiomic feature extraction were performed using LIFEx (version 6.30) (45). All lesions were included for the analysis, namely the primary and metastatic lesions (intra- and extra-thoracic), yielding 1 to 10 lesions as a function of the patient. Lesions were delineated on the PSF-EARL2 PET images using an isocontour at 40% of each lesion's SUV_{max} , then radiomic features were extracted with intensity discretization using a fixed bin width (FBW) of 0.25g/mL ranging from 0–60g/mL of each lesion (the 60g/mL upper bound was higher than the SUV_{max} of all lesions). This combination of image and processing settings was considered the reference settings for radiomic analysis as they were previously

shown to optimize test-retest (19,36,46). Other image settings were explored, including lesion delineation and feature extraction from EARL1 images, lesion delineations with a fixed isocontour at an SUV threshold of 4.0 (SUV4) and a contrast-based isocontour at $0.5 \times \text{SUV}_{\text{peak}} + \text{SUV}_{\text{background}}$ (Contrast; $\text{SUV}_{\text{background}}$ was the mean uptake in a shell located 2cm away from the volume defined at 70% of SUV_{max} , excluding voxels with $\text{SUV} > 4$), and intensity discretization with a fixed bin number (FBN) of 64 bins in a variable range of $\text{SUV}_{\text{min}} - \text{SUV}_{\text{max}}$.

In total, 49 radiomic features from seven classes were extracted (full list given in Supplemental Table 1): six conventional PET metrics (*Conventional*), five shape-based (*Shape*), six histogram-based (*Histogram*), seven grey-level co-occurrence matrix (*GLCM*), eleven grey-level run-length matrix (*GLRLM*), eleven grey-level zone-length matrix (*GLZLM*), and three neighborhood grey-level difference matrix (*NGLDM*). Features were obtained only for lesions that included at least 64 voxels. LIFEx's feature definition follows the IBSI standard results (47,48).

Data Analysis

Features calculated from images obtained at different time-points on the first day of scans were statistically compared using pairwise Wilcoxon signed-rank tests. P-values below 0.05 were considered statistically significant after Benjamini-Hochberg false discovery rate correction. Change in feature value was measured as a function of tracer uptake time by using its test-retest at 60min p.i. as baseline (analogous to a Z-score):

$$Z = \frac{(\text{RF}_{90} - \text{RF}_{60}) - \text{mean}(\text{TRT}_{60})}{\text{sd}(\text{TRT}_{60})}$$

RF_{60} and RF_{90} represent the radiomic feature values at 60min and 90min p.i., respectively. TRT_{60} is the test-retest difference between the feature values at the second- and first-day scans (at 60min p.i.). Therefore, the effects of tracer uptake time on radiomic features were contextualized with respect to its repeatability: Z-

scores lower than 1 indicate changes with uptake time smaller than test-retest variability and Z-scores higher than 1 show a change larger than their repeatability.

A feature was considered repeatable if the intraclass correlation coefficient (ICC; agreement type, two-way mixed-effects model, single rating) between test-retest scans (same reconstruction, delineation method and discretization) was higher than 0.9 at both time-points. A feature was defined as robust against change in tracer uptake time if it was not significantly affected by tracer uptake time after false discovery rate correction and if its value changed from 60-min to 90-min less than it changed from one day to another (i.e. mean Z-score < 1). Finally, features were assigned to a use-case based on their repeatability and susceptibility to tracer uptake time (Figure 1): features that were repeatable and susceptible to tracer uptake time were classified for *Dual-Time-Point* (DTP) studies; repeatable features with uncertain response to tracer uptake time were classified as *Cross-Sectional level 1* (CS1); repeatable features that were robust to tracer uptake time were classified as *Cross-Sectional level 2* (CS2); features with poor repeatability at any time-point were *Discarded*. Statistical analysis was carried using R version 4.0.4.

RESULTS

Feature Dependence on Uptake Time

All *Conventional* features were significantly affected by tracer uptake interval and increased in value with increased uptake time (Figure 2, positive mean Z-score). *Shape* features were not significantly different between the two tracer uptake times. Half of the *Histogram* features were affected by uptake time (note that *Histogram Entropy log10* and *Histogram Entropy log2* are equivalent after re-scaling with Z-scores). 4/7 *GLCM* features significantly increased over time and only one decreased. One *GLRLM*, two *GLZLM* and two *NGLDM* features were not statistically significantly dependent on tracer uptake time (Figure 2). The features of each class with the highest Z-score and statistically significant dependent on tracer uptake time were ($p < 0.05$) *Conventional SUV_{mean}* (average Z-score and standard deviation = 1.36 ± 0.98), *Histogram Entropy* (1.04 ± 0.73), *GLCM Dissimilarity* (1.35 ± 1.29), *GLRLM LRHGE* (1.38 ± 1.69), *GLZLM SZLGE* (-1.24 ± 1.86), and *NGLDM Contrast* (1.28 ± 2.10).

Radiomic Feature Use-Case Classification

94% (46/49) of the features had reliable repeatability ($ICC > 0.9$, Supplemental Figure 1). In total, 35% (17/49) of features were classified as DTP, 39% (19/49) as CS1, 20% (10/49) as CS2, and 6% (3/49) were discarded (Supplemental Figure 1). No *Conventional* feature was classified for CS2 use-case, no *Shape* feature was classified for dual-time-point use, and no *NGLDM* feature was classified for CS1. The remaining feature classes had mixed use-case classification (Figure 3).

Influence of Image Settings on Repeatability and Use-Case Classification

The reference settings (PSF-EARL2 reconstruction, 40% of SUV_{max} delineation and fixed bin width discretization) had less discarded features than other image settings (Figure 4). With EARL1 (and recommended delineation and discretization), images had one less repeatable feature (*NGLDM Coarseness*)

than PSF-EARL2 (Figure 4). With PSF-EARL2 and fixed bin width discretization, the Contrast-based lesion delineation method had poorer repeatability than the other methods and SUV4 had fewer repeatable features than 40% of SUV_{max} (22, 6, and 3 features discarded, respectively). Lastly, FBN had considerably lower repeatability than FBW (22 and 3 discarded features with recommended reconstruction and delineation, respectively; Supplemental Figure 2).

Using the reference delineation and discretization, EARL1 had no *Conventional* feature classified for dual-time-point use-case (Figure 4; Supplemental Figure 3). *Histogram* features were only classified for CS1 use-case (or were discarded) while all *Shape* features were classified for CS2. In total, 8% (4/49) features had dual-time-point classification, 67% (33/49) had CS1, 16% (8/49) had CS2, and 8% (4/49) were discarded with EARL1 reconstruction when using the reference delineation and discretization.

Despite using the reference reconstruction and discretization, the contrast-based approach resulted in 45% (22/49) of features being discarded (Figure 4; Supplemental Figure 3). With SUV4, 12% (6/49) features were discarded, and all repeatable *Conventional* features had dual-time-point classification; other feature classes had mixed use-case classifications.

Using FBN for discretization resulted in different use-case classifications as compared to FBW, even when both used the reference reconstruction and delineation methods (Figure 4). The exceptions to that were the *Conventional* and *Shape* features since those are not dependent on the image intensity discretization (Supplemental Figure 3). With PSF-EARL2, 40% of SUV_{max} and a fixed bin number, only one grey-level-based feature was classified for CS1: *GLRLM RLNU*. Furthermore, all *GLCM* and *NGLDM* features were robust to tracer uptake time with a fixed bin number discretization (CS2 use-case) and all *Histogram* features were Discarded (Figure 4).

DISCUSSION

This study demonstrated that for PET image reconstructed with PSF-EARL2, lesion delineation with 40% of SUV_{max} and intensity discretization using fixed bin width, most (94%) traditional and grey-level-based features were repeatable at both 60 min and 90 min p.i. scans. From the radiomic features assessed, 35% were repeatable and able to detect a change as a function of uptake time (DTP), 39% were repeatable but had an unclear dependency on uptake time (CS1), 20% were repeatable and robust against tracer uptake time changes (CS2), and 6% were not repeatable (Discarded). Additionally, analyses performed on PET images reconstructed using EARL1, lesion delineation using a contrast-based approach or a fixed threshold method, and intensity discretization using a fixed number of bins decreased repeatability and led to different use-case classification of radiomic features.

Overall, more features significantly increased (22/49) with time than decreased (12/49), as found previously (49). *Conventional* features increased over time, as expected (50,51), and *Shape* features slightly decreased in the delayed PET scan. This decrease in volume due to a higher threshold for lesion delineation (at 40% of SUV_{max}) agrees with the lower metabolic tumor volume of breast cancer for delayed PET scans (52). The statistically significant *Histogram* features affected by tracer uptake time were *Energy* (decreased) and *Entropy* (increased). The first is related to the uniformity of the distribution and the second to its randomness, therefore reflecting an increase in tumor heterogeneity at delayed ^{18}F -FDG PET scans (52). Yet, these features were not significantly affected by uptake time on peripheral nerve sheath tumors with relatively low ^{18}F -FDG uptake (49), emphasizing that translation of radiomic results between different tumor types must be carried with caution even with first-order features.

The increase of *GLRLM RP*, *GLZLM ZP*, and *NGLDM Contrast* over time reflects an increased heterogeneity, as *RP* and *ZP* are low for highly uniform VOIs (47) and *Contrast* is related to the intensity difference between neighboring regions. However, there was a decrease in *GLRLM* and *GLZLM non-uniformity*, which suggests a reduction in heterogeneity over time. These non-uniformity features have been previously reported as being dependent on time (49,52), but with a small effect size and a direction of

change that was not uniform across studies. Therefore, more features suggest an increase in tumor heterogeneity over time than decrease, agreeing with previous findings for advanced breast cancer (52) but disagreeing with peripheral nerve sheath tumors results (49). This incompatibility may come from the tracer uptake levels in the tumors. The present study and Garcia-Vicente et al. (52) assessed tumor with relatively high ^{18}F -FDG uptake and found increasing heterogeneity over time, while Lovat et al. (49) studied low tracer uptake lesions.

Radiomic features classified for CS1 use-case were repeatable at both tracer uptake times but did not have any clear relationship with tracer uptake time, i.e., were neither robust nor sensitive. These features may be suitable for cross-sectional studies if all images are acquired with similar post-injection times. The dependence of the CS1 features on time could explain some of their variability and range previously found on lung cancer assessment (15,25,46). Other repeatable features were robust against changes in tracer uptake time (CS2) and are recommended for studies with inconsistent post-injection scanning time. In contrast, repeatable features statistically significantly and substantially affected by tracer uptake time were classified for dual-time-point use-case. Like CS1 features, dual-time-point features may be used on images acquired with similar tracer uptake time (e.g., SUV_{mean}), but can also measure the effect of time on feature values. Previous studies have reported a possible added benefit of a dual-time-point scanning protocol for differentiation between benign and malignant pulmonary lesions with textural features (39,40) and for breast cancer intra-tumoral heterogeneity assessment (52). Unfortunately, given the different nature of the lesions and analysis settings in those previous studies, it is not possible to directly compare the radiomic features found useful by these authors with the ones we identified as appropriate for dual-time-point studies.

As shown previously (19), EARL1 reconstructions resulted in worse repeatability than PSF-EARL2. Additionally, PSF-EARL2 reconstructions also display higher heterogeneity (20) and are recommended for textural analysis. Concerning the lesion delineation method, a fixed isocontour lesion delineation (SUV_4) yielded poorer repeatability than an adaptive threshold based on 40% of SUV_{max} as expected from the literature (36). The contrast-based delineation had the poorest repeatability of all methods

and is thus not recommended for radiomics. Furthermore, previous findings that an FBW intensity discretization has a superior repeatability for PET radiomics than FBN were reproduced (19,46,47). For historical cohorts where only EARL1 reconstruction is available, few features are viable for dual-time-point studies (Figure 4). With lesion delineation at 40% of SUV_{max} and discretization with FBW, EARL1 protocol still provides several repeatable radiomic features.

The analysis of data from a single scanner vendor and the inclusion of a single tumor type (NSCLC, including intra- and extra-thoracic lesions), especially given that features have different expression for different cancer types, are some limitations of our study and multi-center studies are needed to verify our findings. Furthermore, lesion delineation is affected by differences in voxel size, which impacts radiomic feature values, but not necessarily the use-case classification of features, although this would need to be explored. Data from static scans 30min apart was evaluated. Nevertheless, it is possible that additional radiomic information could be obtained from scans acquired further apart in uptake time. Finally, several features were analyzed under different image conditions on only 10 subjects. This study may thus be subject to type 1 errors although a false discovery rate correction was applied to the statistical analysis.

In summary, EARL1 reconstruction led to fewer features being classified for dual-time-point use-case than PSF-EARL2. Textural features were not robust against changes in tracer uptake interval when SUV_4 was used for lesion delineation, showing that for NSCLC radiomics, this method should only be applied to PET images acquired with a similar uptake time. Furthermore, most features were discarded when using the contrast-based delineation method or the FBN intensity discretization and their use is not recommended for NSCLC ^{18}F -FDG PET radiomic studies.

CONCLUSION

This study demonstrated that PET radiomics can be repeatable, summarized the features' susceptibility to post-injection PET scanning time, and classified the features into reliable use-cases for NSCLC radiomics: dual-time-point and cross-sectional studies. Repeatability and use-case of radiomic features depended on PET image reconstruction, lesion delineation and intensity discretization, and recommendations were provided accordingly.

KEY POINTS

Question: Is the change of radiomic features with ^{18}F -FDG uptake time larger than their repeatability and can that be used for temporal textural analysis?

Pertinent findings: PET image reconstruction with PSF modelling, lesion delineation at 40% of SUVmax and intensity discretization with fixed bin width resulted in repeatable radiomic features at 60min and 90min post-injection scans and provided reliable information for cross-sectional and dual-time-point studies.

Implications for patient care: Radiomic features were identified and classified for potential use-cases in cross-sectional and dual-time-point protocols, providing reliable information about tumor heterogeneity for non-small cell lung cancer assessment.

Figures

Figure 1: Flow chart for use-case classification of radiomic features. TRT: test-retest, ICC: intraclass correlation coefficient.

Figure 2: Effect of tracer uptake time on radiomic features. Left: distribution of Z-scores for each feature. Z-scores were calculated using the test-retest at 60 min post-injection scan as the baseline. Right: mean Z-score of each feature (dot indicates statistical significance). Analysis of images with reference settings.

Figure 3: Percentage of radiomic features with each use-case classification for each feature class. Classifications are: Cross-Sectional level 1 (CS1), Dual-Time-Point (DTP), Cross-Sectional level 2 (CS2), and Discarded. Analysis of images with reference settings.

Figure 4: Percentage of radiomic features with each use-case classification for each feature class in all image settings configurations. Columns of panels show different lesion delineation methods and rows show different image reconstructions and intensity discretization strategies. Classifications are: Cross-Sectional level 1 (CS1), Dual-Time-Point (DTP), Cross-Sectional level 2 (CS2), and Discarded. Analysis of images with reference settings are shown in the top left.

Graphical Abstract

Supplemental Table 1: Radiomic features

Feature class	Feature name
Conventional	SUV _{max} : Maximum SUV SUV _{mean} : Average SUV SUV _{min} : Minimum SUV SUV _{peak} : Peak SUV on a 1 mL sphere SUV _{std} : Standard deviation of SUV TLG: Total lesion glycolysis
Shape	Compacity Sphericity Surface (mm ²) Volume (mL) Volume (vx)
Histogram	Energy; Uniformity Entropy (log10) Entropy (log2) Excess Kurtosis Kurtosis Skewness
Grey-Level Cooccurrence Matrix (GLCM)	Contrast; Variance Correlation Dissimilarity Energy; Angular Second Moment Entropy (log10) Entropy (log2); Joint entropy Homogeneity; Inverse Difference
Grey-Level Run-Length Matrix (GLRLM)	GLNU: Grey-level non-uniformity (for run) HGRE: High grey-level run emphasis LGRE: Low grey-level run emphasis LRE: Long-run emphasis LRHGE: Long-run high grey-level emphasis LRLGE: Long-run low grey-level emphasis RLNU: Run-length non-uniformity RP: Run percentage SRE: Short-run emphasis SRHGE: Short-run high grey-level emphasis SRLGE: Short-run low grey-level emphasis
Grey-Level Zone-Length Matrix (GLZLM)	GLNU: Grey-level non-uniformity (for zone) HGZE: High grey-level zone emphasis LGZE: Low grey-level zone emphasis LZE: Long-zone emphasis LZHGE: Long-zone high grey-level emphasis LZLGE: Long-zone low grey-level emphasis SZE: Short-zone emphasis SZHGE: Short-zone high grey-level emphasis SZLGE: Short-zone low grey-level emphasis ZLNU: Zone length non-uniformity ZP: Zone percentage
Neighbourhood Grey-Level Different Matrix (NGLDM)	Busyness Coarseness Contrast
